Graphical Linking of MO Multicenter Bond Index and VB Structures. II- 5-c Rings and 6-c Heterocyclic Rings

Carlos Guido Bollini,[1,2] Mario Giambiagi,[3] Myriam Segre de Giambiagi,[3,4] and Aloysio Paiva de Figueiredo[3]

Through the graphical method proposed, it is possible to create a link between an MO multicenter bond index and VB structures. The value of the index depends on the order of the atoms involved, if there are more than three. For 5-c rings, three basic structures are required; the eventually different values are 12. Unlike the 6-c case, it may happen that different pairs of basic structures are used to build the same polygon. For the 6-c rings, including heteroatoms, the original degeneracy of benzene splits, leading eventually to 60 different I_{ring} values.

KEY WORDS: MO multicenter bond index; VB structures; 5-*c* rings; 6-*c* heterocyclic rings.

INTRODUCTION

Molecular orbital (MO) theory has dealt with chemical bonds since Hückel, who already recognized the possibility of multicenter bonds, such as that of the allyl cation [1]. The valence bond methods initially enjoyed more popularity among chemists than MO models, the classical VB structures seeming closer to chemical intuition. Both viewpoints are now seen as complementary, rather than opposed to each other [2].

Several years ago, we proposed a generalization of the Wiberg index [3] to nonorthogonal basis [4], extended later so as to take into account multicenter bonds [5]. We have applied multicenter bond indexes to different questions as, for example, the estimation of aromaticity [6]. Multicenter bonds have, of course, drawn the attention of many authors. Let us mention, among them, the treatment of increased valence structures extensively used by Harcourt [7] and the geminal expansion of pair densities [8].

Our multicenter index $I_{ABC...L}$ depends on the *AB ... L* order [9], except for the 3-c (three-center) case. In a previous paper, we proposed an interpretation of these different possible values for benzene, linking graphically the MO multicenter index to VBS in a very appealing fashion [10].

The 5-c ring, with 6π electrons, poses quite different questions concerning VBS. This is the main subject of the present work. We also study the 6-c rings, including heteroatoms; the lower symmetry compared with that of benzene leads to the splitting of degeneracy into several values.

THE GRAPHICAL METHOD

Let us briefly discuss the definitions required. For an *N*-electron molecule and closed shells, the MO multicenter bond index $I_{ABC...L}$ is defined as [5]

$$I_{ABC...L} = 2^L \sum_{a \in A, b \in B, ..., \ell \in L} \Pi_a^b \Pi_b^c ... \Pi_\ell^a \quad (1)$$

$$\Pi_a^b = \sum_i x_{ia}x^{ib}; \qquad N = 2Tr(\Pi) \qquad (2)$$

and $x_{ia}(x^{ib})$ are the covariant (contravariant) coefficients of the ith occupied MO.

For a usual bond (2-c), I_{AB} is the generalization of the Wiberg index [3] to nonorthogonal basis [4]. The Π matrix consists of submatrices, such as Π_{AB} for any pair of atoms, so that Eq. (1) may also be written as

$$I_{AB\ldots L} = 2^L Tr(\Pi_{AB}\Pi_{BC}\ldots\Pi_{LA}) \qquad (3)$$

In Part I [10], we have shown how to link the different values arisen from an MO calculation estimating $I_{AB\ldots L}$ to classical VB structures, through Rumer-type diagrams [11]. For benzene, used to illustrate the graphical method, the basic structures yielding the involved polygons are both the canonical structures and non-canonical ones.

If the L-center bond is represented by drawing the L centers on a circle, the L-center index is a number corresponding to a closed broken line joining the points $AB\ldots LA$ (Fig. 1). A different $AB\ldots LA$ order may match with different polygons. A bond is an arrow in a VB structure and a matrix Π_{AB}; the inverted arrow is the transposed matrix. Thus, an $AB\ldots LA$ order is a polygonal path. It is easily seen that any cyclic permutation yields the same value; the anticyclic order, which amounts to transposing Eq. (3), leading to the same trace, gives also the same value. That is, in the drawing, the broken line may start from any of the L points, in cyclic or anticyclic order. Thus, in the illustration of Fig. 1 for benzene,

$$\begin{aligned} I_{145236} &= 2^6 Tr(\Pi_{14}\Pi_{45}\Pi_{52}\Pi_{23}\Pi_{36}\Pi_{61}) \\ &= 2^6 Tr(\Pi_{61}\Pi_{14}\Pi_{45}\Pi_{52}\Pi_{23}\Pi_{36}) = I_{614523} \\ &= I_{632541} = 2^6 Tr(\Pi_{63}\Pi_{32}\Pi_{25}\Pi_{54}\Pi_{41}\Pi_{16}) \quad (4) \end{aligned}$$

I_{145236}

Fig. 1. Representation of a six-center index for benzene and the corresponding VB structures.

It is thus enough to calculate $L!/2L = (L-1)!/2$ values, instead of the $L!$ possible permutations. For benzene, the 720 permutations reduce to 60 possible different values; these correspond to 60 geometrical configurations, which we have related to valence bond structures (VBS). For five centers, the eventually different configurations are $4!/2 = 12$.

FIVE-CENTER RINGS

We shall deal with a ring involving five centers and 6π electrons. If we denote by f the number of first-neighbor linked atoms and by s the second-neighbors, the twelve configurations may be grouped in four types, as shown in Fig. 2: (a) $5f$; (b) $3f + 2s$; (c) $2f + 3s$; (d) $5s$. We can relate each configuration to a certain VBS; this one may depend on the initial position. We obtain thus (a) 1; (b) 2–6; (c) 7–11; and (d) 12.

We have chosen to define three types of basic structures, shown in Fig. 3: Kekule (K), Dewar (D), and

Fig. 2. Geometrical configurations and VB structures for five-center rings; f, first-neighbor atoms; s, second-neighbor atoms.
Fig. 3. Basic structures yielding the configurations of Fig. 2.

Fig. 4. Building the configurations of Fig. 2 from the basic structures of Fig. 3.

Modified (M), the last one being noncanonical. They lead to the configurations of Fig. 2, as shown in Fig. 4; as we shall see further, the way of doing this is not unequivocal.

The Rumerlike diagrams need to be adapted in the odd case. The branching diagrams for the 5-c case are usually described for 5π electrons [12]; McWeeny uses diagrams with crossed arrows as independent functions, stating that although they are not the most usually adopted, they are perfectly acceptable as basis functions [12]. In order to use the Rumer method when the number of orbitals to be paired is odd, a phantom orbital is also sometimes added and its contribution is subtracted at the end [13, 14]. Or else, one more point is added, the *pole* [11].

For five centers and 6π electrons, the MO approach adds the sixth electron to the delocalized electron pool. There is thus no lone electron pair, but rather a higher concentration of electronic density around the most electronegative atom; otherwise, the exceeding electronic density is spread along the ring. The VBS have two bonds and a lone pair. The graphical method, which we propose as a link between both viewpoints, is halfway between them.

This is done in Fig. 4 according to the following convention for the ABCDE order. The polygonal path starts from position 1; atom 1 is linked to two other atoms in the polygon, the second one being the atom with the lowest label. A cyclic permutation, say EABCD, leads to another VBS, both being complementary in the sense that the polygon is obtained superimposing two VBS. The fifth side of the polygon links the dot of the first VBS to the dot of the second one. One certain VBS may appear twice in the possible configurations; this would mean that it contributes to the I_{ring} value in both cases.

In benzene, due to the unique symmetry of the system, each of the twelve polygons could be unequivocally built from two of the basic structures. For five centers, the polygons are only four, but the way to build them with the adopted convention is not unequivocal. Thus, it
is shown in Fig. 4 that, while polygonal (a) is K + K, polygonal (b) may be obtained either as K + M, D + K or D + D; polygonal (c), in turn, is found as M + K, M + D or D + D. Finally, polygonal (d) is M + M.

This pattern is quite different from that, much simpler, of benzene.

We shall limit our discussion to two alternatives: (1) the five centers are occupied by atoms of the same nature (cyclopentadienyl anion) and (2) a "first perturbation" is added, i.e., a heteroatom (pyrrole, furan, and thiophene).

Case I

As seen in Table I, only four values are obtained in this case for the twelve eventually different configurations. The type (a) value for the cyclopentadienyl anion is 0.11451. Configurations 2–6 of Fig. 2 are here equivalent for, independently of the different VBS which each of them give place to, all the polygons may be superimposed in the same figure by successive 72° rotations around the pentagon center. In group theory terms, symmetry operations bring the broken line polygons into coincidence [15]. We have, hence, the single value of 0.01654 for type (b) configurations.

For the same reason, we have again fivefold degeneracy for type (c) values ($2f + 3s$), i.e., -0.00631. Finally, type (d) ($5s$), as type (a), can give only one value.

For this homonuclear case, type (a) configuration can only be represented by Kekule VBS with spin alternation. Similarly, only the basic structure M arises for (d), without spin alternation. For types (b) and (c), the three basic structures appear; in type (b) only D structures allow spin alternation, while in type (c) this applies to the K structure.
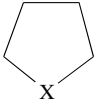

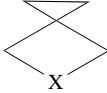

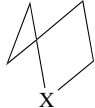

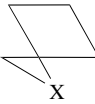

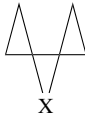

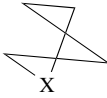

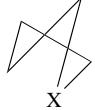

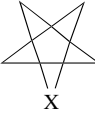

Case II

We have drawn in Fig. 5 the twelve configurations corresponding to those in Fig. 2, when a heteroatom is placed at position 1. The degenerate (b)- and (c)-type configurations now split into three different possible index values in each case, as II = V and III = IV.

The different VBS that may arise for each configuration of Fig. 5, depending on the initial ring position, are shown in Fig. 6. The first column starts from position 1, the second from the second position along the polygon path, and so on. Thus, the configurations aI, bI, cI, and dI are related to five VBS, but $\delta = \gamma$ and $\eta = \theta$. In the ground state, described by aI, these three Kekule-type VBS are precisely those most heavily contributing to the ground state of this kind of molecule. From what precedes, twice the "weight" of ϵ would be ascribed to δ and η. Similar considerations regarding "weights" may be applied to bI, cI, and dI. The VBS for bII (= bV) and bIII (= bIV) may be also obtained straightforwardly. The five different VBS have now the same "weight;" the same thing holds for cII (= cIV) and cIII (= cV).

In the ground state which, as we have just mentioned, is described by aI, the K-type VBS show spin alternation. As we had seen for benzene, and is remarked

Table I. The Different I_{ring} Values for Typical 5-*c* Rings[a]

| Configuration | Type | I_{ring} | | | |
		X = CH	X = NH	X = O	X = S
	aI	0.11451	0.09618	0.05414	0.06951
	bI	0.01654	0.00234	0.00011	0.00034
	bII		0.00990	0.00495	0.00492
	bIII		0.02360	0.01291	0.01846
	cI	-0.00631	-0.01522	-0.01392	-0.01692
	cII		-0.00366	-0.00101	-0.00154
	cIII		-0.00161	-0.0044	-0.00038
	dI	-0.00092	-0.00039	-0.00010	-0.00011

[a] X = CH cyclopentadienyl anion; X = NH pyrrole; X = O, furan; X = S thiophene. For X = CH, all type *b* and all type *c* configurations are equivalent; in the other molecules, for *b* and *c*, II = V and III = IV.

by other authors [16], the ground state shows a dominant role of spin alternation. In bI, bII, and bIII, only D-type

Configurations

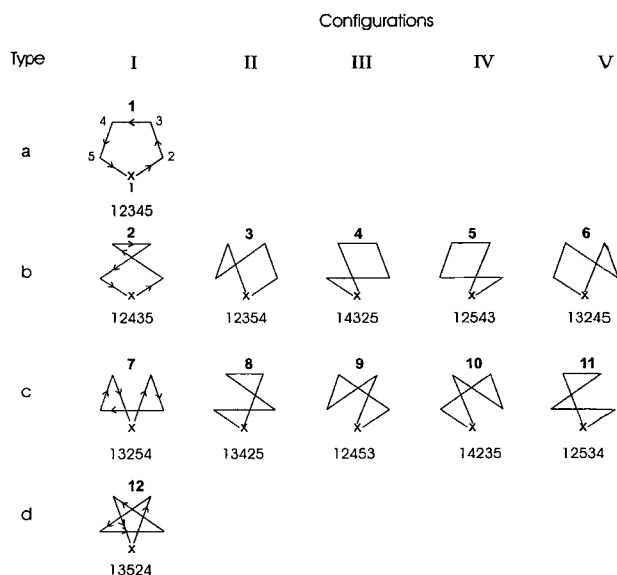

Fig. 5. The configurations for a 5-c ring with a heteroatom in position 1.

VBS

Fig. 6. Possible VBS for each different configuration of Fig. 5.

VBS show spin alternation, while in cI, cII, and cIII it takes place only in K-type structures.

Finally, for (d) only crossing VBS appear, with no spin alternation.

We have reported in Table I, the 5-c- I_{ring} values for all configurations of the molecules mentioned in this section. It is manifest that the discrimination between otherwise degenerate values issues from the loss of symmetry when a heteroatom is introduced in the 5-c ring.

It is easily seen from Eq. (3) that, if there is $\sigma - \pi$ separation, the submatrices being block-diagonal in σ and π, it can be written

$$I = I^{\sigma} + I^{\pi} \qquad (5)$$

As it happened with benzene, I_{ring} is mainly π also for the 5-c rings. One could wonder if a π calculation would suffice. Yet, we have obtained elsewhere a quite different picture for the highly strained 3-c rings [17], where I_{ring} is mainly σ in nature. Accordingly, the notion of σ aromaticity is applied to such systems [18].

SIX-CENTER HETEROCYCLIC RINGS

We have mentioned that for a 6-c ring, we may eventually obtain up to 60 different values for I_{ring}. Due to the highly peculiar symmetry of the system, for benzene they are actually 12 (Fig. 7). In Fig. 7, as in our previous reference [10], the configurations have been ordered according to the number of the involved first-neighbor (*o* for *ortho*), second-neighbor (*m*, *meta*), and third-neighbor (*p*, *para*) linked atoms. As for the pentadienyl anion, for each one of the twelve configurations in benzene, successive 60° rotations around the system center lead to the same diagram, superimposed with the first one.

The introduction of heteroatoms in the benzene hexagon splits the degenerated values from the 12, found for benzene, up to 60 values when there is no symmetry. In this work, the examples chosen are the monocyclic azines.

We illustrate in Fig. 8 the behavior of group (c) values, i.e., configurations 8 to 10 of pyridine and of 1,3,6-triazine. As for benzene [10], the VBS corresponding to this polygon are the Dewar ones, exhibiting spin
Fig. 7. Geometrical configurations for six-center rings; *o*, (ortho), *m* (meta), *p* (*para*) types of neighbors.

Fig. 8. Splitting of degeneration in configurations (c) of Fig. 7, for pyridine and 1,3,6-triazine. For pyridine, configurations 9 and 10 are equivalent; for 1,3,6-triazine, they are not. The VBS are shown for pyridine.

alternation and the second highest I_{ring} value. The polygons of configurations 9 and 10 of pyridine may be superimposed by successive 60° rotations; for 1,3,6-triazine this is not possible. Accordingly, the benzene value of 0.02197 becomes 0.02359 for configuration 8 and 0.02073 for configurations 9 and 10, respectively, in pyridine. The corresponding values for this asymmetric triazine are respectively 0.02467, 0.02131, and 0.01839. Turning back to pyridine, the weight of VBS ($\square$) is twice that of VBS (#), as it should.

We have reported in Table II, the number of different I_{ring} values for each one of the monocyclic azines corresponding to the different symmetry cases; they are compared to benzene. As symmetry decreases, the number of different values increases up to the 60 different values for 1,3,6-triazine, a molecule belonging to the C_s group.

For 1,3,5-triazine (D_{3h}), there is only one more value than the 12 for benzene; it arises within the d* configurations (11 to 22). We show it in Fig. 9 (i): a 60° rotation of configuration 11 in the counterclockwise direction yields a configuration that cannot be superimposed with the former one.

The molecules belonging to the C_{2v} group exhibit two kinds of cases, depending on whether the symmetry axis passes (or not) through two atoms in the molecule. Pyridine and pyrimidine belong to the first kind, while pyridazine belongs to the second one. In the first kind, the π system has four symmetric and two antisymmetric basis functions, while the second kind of system has three of each. The first has a lower number of different

Table II. Distribution of the Different $\mathcal{N}$ Values for Benzene and Sample Monocyclic Azines[a]

Molecule	Sym.	$\mathcal{N}$	a	b	c	d*	d**	e	f*	f**	g	h	i	j
Benzene	D_{6h}	12	1	1	1	1	1	1	1	1	1	1	1	1
1,3,5-triazine	D_{3h}	13	1	1	1	2	1	1	1	1	1	1	1	1
Pyrazine	D_{2h}	24	1	2	2	3	2	1	2	2	3	2	2	2
Pyridine	C_{2v}	32	1	3	2	6	3	1	2	3	3	3	3	2
Pyrimidine	C_{2v}	32	1	3	2	6	3	1	2	3	3	3	3	2
Pyridazine	C_{2v}	38	1	4	2	6	4	2	2	4	3	4	4	2
1,3,6-triazine	C_{s}	60	1	6	3	12	6	2	3	6	6	6	6	3

[a] See Fig. 7.

I_{ring} values from the second one; we show an example in Fig. 9(ii). In one d** configuration, a rotation leads to the same diagram in pyrimidine and to a new diagram in pyridazine.

Hence, it is possible, through graphical arguments, to predict the number of different I_{ring} values, which may appear within the 60 eventual possibilities. The 6-c case affords an appealing illustration of the method.

CONCLUSIONS

1. For 5-c rings, we are led graphically to four different values for I_{ring}, if all the ring atoms are equal and to eight values if the ring includes a heteroatom.

2. For 5-c rings it may occur that different pairs of basic structures are used to build the same polygon.

3. The highest I_{ring} value corresponds to Kekule-type structures in VB terms.

4. For 5-c rings, I_{ring} is mainly π.

5. For 6-c heterocycles, the graphical method helps to understand and predict the different I_{ring} values arising as symmetry is lowered, starting from benzene (12 values) up to 1,3,6-triazine (60 values).
