#### Abstract

The Open Shop Scheduling Problem (OSSP) is one of the most interesting, complexes and not frequently approached scheduling problems. Due to its intractability with other techniques, in this work we present an evolutionary approach to provide approximate solutions.

One of the most important points in an Evolutionary Algorithm is to determine how to represent individuals of the evolving population and then to decide suitable genetic operators. In this work, we use permutations as chromosomes. Dealing with permutations requires appropriate crossover operators to ensure feasible offspring. Usual operators are partially-mapped, order, cycle and one-cut-point crossover. The goal is to determine which is the most adequate for facing the OSSP with a simple evolutionary algorithm. Several known instances have been considered for testing in order to evaluate the algorithm behavior.

Keywords: Open Shop Scheduling, Evolutionary Computation, Crossover.

[^0]
## 1. Introduction

Evolutionary algorithms (EAs) can be used as techniques to solve problems inspired in natural evolution [4]. In an EA, a data structure, representing a feasible solution to a problem, is defined. Each possible data set admissible for that structure would be a potential solution to the problem. An EA behave as a search method, where the solutions to the problem are able to reproduce between them, combining characteristics and generating new solutions.
EAs have proved their ability to solve difficult scheduling problems. One of the most frequent models taken from real life is known as open shop. An Open Shop Scheduling Problem (OSSP) involves a collection of $m$ machines and a collection of $n$ jobs. Jobs can follow routes, which are open and arbitrarily decided by the scheduler. Each job consists of a set of operations, sometimes called tasks [8, 6]. Each machine can process at most one operation at a time and each job can be processed by at most one machine at any given time. The order in which the jobs are processed on the machine, can be chosen arbitrarily; but two or more tasks from the same job cannot be processed on the same machine. The objective in our OSSP is to determine a feasible combination of the machine and job orders, a schedule, which minimizes the overall finishing time, also known as the makespan. The makespan cannot be less than the maximum workload of each machine or the total processing time needed of $n$ jobs.
Consider an OSSP where there are two machines and $n$ jobs, denoted as 02||Cmax [6]. The makespan has to be minimized. Job $j$ may be processed first on machine 1 and then on machine 2 or vice versa; the decision maker may determine the routes. With only two jobs, it can be easily verified that there are only two possible schedules and both have the same makespan. If $n>3$ the problem belongs to the class of NP-hard problems.
The OSSP has many applications, specially in the manufacturing world and in industry. The common example is that of an automotive repair shop [10]. In such a shop, a typical job might involve the operations "spray-paint", and "change-tyres" to be performed on the same vehicle. These operations cannot usually be performed concurrently (especially if the stations at which these operations are performed are in different places, for instance), but can be performed in any order. Also it is usually true that different stations (i.e. "machines") can concurrently process operations from different jobs (e.g. involving different vehicles). If the operations in a job must be performed in some fixed order, then this becomes a Job Shop Scheduling Problem (JSSP).
In this work, we study the performance of evolutionary algorithms using different crossover operators, which are suitable for permutation representation.
The work is organized as follows. Section 2 presents a detailed problem description. Sections 3 and 4 describe the adopted representation and the crossovers methods implemented. Section 5 gives details on the experiments and section 6 discusses the results reached. Finally, conclusions and future works are presented.

## 2. The Open Shop Scheduling Problem

The OSSP consists of $m$ machines $M_{1}, M_{2}, \ldots, M_{m}$ and $n$ jobs $J_{1}, J_{2}, \ldots, J_{n}$. Each job $J_{i}$ consists of $m$ operations $O_{i j}$, The processing times are giving in an $m x n$ matrix $P$ where $p_{i j}$ indicates the duration of the operation $O_{i j}$ for the job $j$ on the machine $i$, without preemption.
Operations for a job can be processed in any order, but only one at any giving time. We assume that each machine can process at most one operation at a time and each job can be processed by at most one machine at any given time. The order, in which the job is processed by the machines, can be chosen arbitrarily. The objective function to be minimized is the maximum time that is necessary to complete all jobs, or makespan.
An example follows. Table 1 describes a possible instance for the problem with 4 machines and 4 jobs. Table 2 shows a possible allocation of operations on the machines, and the corresponding Gantt diagram is showed in figure 1.

| Machine | Job J0 | Job $\boldsymbol{J 1}$ | Job J2 | Job J3 |
| :---: | :---: | :---: | :---: | :---: |
| $\boldsymbol{M 0}$ | 34 | 15 | 38 | 95 |
| $\boldsymbol{M 1}$ | 2 | 89 | 19 | 7 |
| $\boldsymbol{M 2}$ | 54 | 70 | 28 | 34 |
| $\boldsymbol{M 3}$ | 61 | 9 | 87 | 29 |

Table 1. A $4 \times 4$ benchmark problem for the OSSP.

| Machine | Job | Operation | Operation <br> Length | Start time | End time |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $M 3$ | $J 1$ | $O_{31}$ | 9 | 0 | 9 |
| $M 0$ | $J 1$ | $O_{01}$ | 15 | 9 | 24 |
| $M 2$ | $J 3$ | $O_{23}$ | 34 | 0 | 34 |
| $M 1$ | $J 3$ | $O_{13}$ | 7 | 34 | 41 |
| $M 1$ | $J 2$ | $O_{12}$ | 19 | 0 | 19 |
| $M 2$ | $J 1$ | $O_{21}$ | 70 | 34 | 104 |
| $M 3$ | $J 0$ | $O_{30}$ | 61 | 9 | 70 |
| $M 1$ | $J 0$ | $O_{10}$ | 2 | 70 | 72 |
| $M 0$ | $J 2$ | $O_{02}$ | 38 | 24 | 62 |
| $M 0$ | $J 3$ | $O_{03}$ | 95 | 62 | 157 |
| $M 2$ | $J 0$ | $O_{20}$ | 54 | 104 | 158 |
| $M 0$ | $J 0$ | $O_{00}$ | 34 | 157 | 191 |
| $M 1$ | $J 1$ | $O_{11}$ | 89 | 104 | 193 |
| $M 3$ | $J 2$ | $O_{32}$ | 87 | 70 | 157 |
| $M 3$ | $J 3$ | $O_{33}$ | 29 | 157 | 186 |
| $M 2$ | $J 2$ | $O_{22}$ | 28 | 158 | 186 |

Table 2. A schedule for the benchmark problem in table 1 with the makespan value of 193

Figure 1. A schedule for the benchmark problem, OSSP $4 \times 4$, with minimum makespan.

## 3. Chromosome Representation

In this work we are using permutations for the chromosome representation: to each operation of a job is given a unique number. We first enumerate the operations of job $J_{I}$, then the operations of job $J_{2}$, and so on. Thus, for a problem with 4 jobs and 4 machines, the first operation of job $J_{l}$ will be given number 0 , and the last operation of job $J_{4}$ will be given number 15 . For individual chromosomes of the EA, we use strings of length $p$, where $p$ is the total number of operations involved. A scheduling of the operations is represented by using an integer string, $y 1, y 2, \ldots, y_{p}$, where the value of $y_{i}$ represents the operation to be scheduled next. Thus, if we have 4 jobs and 4 machines, the following string (figure 2) represents a possible schedule of the sixteen operations.

| 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 4 | 5 | 13 | 14 | 9 | 7 | 2 | 3 | 8 | 12 | 0 | 1 | 6 | 11 | 15 | 10 |

Figure 2. A chromosome representation for a $4 \times 4$ instance of OSSP.

This representation is interpreted as follows. First, it schedules the operation that has number 4 (the first operation of $J_{l}$ ), then, the operation with number 5 (the second operation of $J_{l}$ ), and so on.
The procedure for calculating makespan consists in scheduling the operations with the goal of finishing an operation at the earliest possible time. This is not as obvious as it might seem. Consider the following scenario (see Figure 3): we want to schedule operation $O_{c}$ from job $J_{c}$ of length $t$ on machine $M_{j}$. Our algorithm scans the operations that have been already scheduled on $M_{j}$. In case a "gap" exists between two consecutive operations, $O_{a}$ and $O_{b}$, such that $y-x>=t$ (where $x$ is the completion time of $O_{a}$ and $y$ is the start time of $O_{b}$,) then the algorithm checks if the operation $O_{c}$ can be scheduled between $x$ and $y$. This is done, only if no other operation from job $J_{c}$ is currently being processed on some other machine between times $x$ and $y$.
If no such gap exists, then operation $O_{c}$ is scheduled sometime after the last operation that was processed on machine $M_{j}$.

Figure 3. Scheduling operation c between operations a and b on machine $M j$.

## 4. Crossover Operators

For this work we select the permutation representation and then in order to obtain feasible schedules after each recombination, adequate genetic operators are needed. They are:

- partial-mapped crossover (PMX). PMX was proposed by Goldberg and Lingle [2] and can be viewed as an extension of two-point crossover for binary string to permutation representation. It uses a special repairing procedure to resolve the illegitimacy caused by the simple two-point crossover. Thus the essentials of PMX are a simple two-point crossover plus a repairing procedure.
- order crossover (OX). OX was proposed by Davis [1]. It can be viewed as a variation of PMX with a different repairing procedure.
- cycle crossover (CX). CX was proposed by Oliver, Smith and Holland [5]. Essentially it can be viewed as a class of uniform crossover to permutation representation together with a repairing procedure. It takes some alleles from one of the parents and selects others from the other parent. Alleles of the first parent are selected in order to define a cycle according to the positions between the parents.
- one-cut-point crossover (OCPX). OCPX was proposed by Reeves [7]. It is a kind of one-point crossover for permutation representation. It defines a cut point, and then takes all the alleles from the first parent until that position and completes the offspring with the alleles according to their occurrence in the other parent.

## 5. Experiments

The algorithms were tested for a set of selected instances of the Open Shop Scheduling Problem that are well known in the literature [9], Taillard gives the pseudocode to generate the individual problem instances. We implemented, in Borland C, Taillard's algorithm and executed it to generate 40 benchmark problems. The generator takes as input: time seed, machine seed and the problem size, which are specified in 9]. We have worked with all the instances for small size problems ( $4 \times 4$ and $5 \times 5$ ) and the medium size problems ( 7 x 7 and 10 x 10 ). For each instance, a series of fifty runs were performed for each crossover operator (OCPX, OX, CX, PMX). The EA used proportional selection for mating. For mutation, a simple interchange operator, which randomly exchanges genes of the chromosome, was designed. The population size was fixed at 100 individuals for all instances. The maximum number of generations was fixed at 1000 and probabilities for crossover
and mutation were set at 0.8 and 0.1 , respectively. These values were determined as the best combination of probabilities after many initial trials.
The following relevant performance variables were chosen:
$>$ Ebest $=(\operatorname{Abs}($ opt_val - best value $) /$ opt_val $) 100$
It is the percentile error of the best found individual when compared with the known, or estimated, optimum value opt_val. It gives us a measure of how far the best individual is from that opt_val.
$>\mathbf{E p o p}=(\operatorname{Abs}($ opt_val- pop mean fitness) $/$ opt_val $) 100$
It is the percentile error of the population mean fitness when compared with opt_val. It tell us how far the mean fitness is from that opt_val.
> \#Opt $=$ It indicates the number of times that the known, or estimated, optimum value is obtained during several experiments made.
> MEbest and MEpop indicate the mean values for Ebest and Epop, respectively.

## 6. Results

Tables 3 and 4 report the results of the algorithm using different crossover methods on the $4 \times 4$ instances. In all of them, the optimum value for each instance was reached, independently of the crossover type; the exception was in the instance Mat43 under the CX, but the Ebest value (0.8) is very close to the optimum. Analyzing \#Opt, OX obtained the biggest number of occurrences in most cases, followed by PMX, OCPX and finally CX. Now considering mean Ebest, best results are obtained with OX, followed by PMX, OCPX and CX.

Table 4. epop results for $4 \times 4$ instances.
Table 4 details Epop results. Lower values were found with CX, varying between 2.7 and $13.8 \%$; this indicates that the population is fairly centred on the best-found value (as we saw previously, in
only one instance the optimum value was not reached). Then, it is followed by OCPX, which shows an error ranging between 6 and $23 \%$. Higher Epop values are observed with the application of OX and PMX, whose values are almost twice as much those showed by other methods.
Although OX obtained the best Ebest results, the population behaves better with CX in average.
Table 5 exhibits results on the $5 \times 5$ instances. Here, only both Mat50 instance under CX and Mat51 under OX reached the optimum value. Best results were achieved by OCPX, CX and OX, but no one brings out the other. Analyzing MEbest values, OCPX presents good results, followed for CX, OX and PMX.
Epop values on the $5 \times 5$ instances are described in table 6. The lowest levels of Epop were found with CX, whose values go from 6.2 to $11.21 \%$; OCPX follows it with an error ranging between 32.4 and $44.3 \%$. Remaining crossover methods exhibit Epop values all over 50\%, but results reached for PMX are the worst ones.
Evaluating results obtained on $7 \times 7$ instance (table 7), a crossover ranking can be established considering Ebest results: CX, OCPX, OX and finally PMX. The latest two show remarkable higher errors. The same ranking can be observed for mean Ebest values.
Analyzing Epop values (table 8) the same crossover ranking is preserved here. Moreover it matches the same ranking presented on previous $4 \times 4$ and $5 \times 5$ instances
Tables 9 y 10 introduce results corresponding to $10 \times 10$ instances. Here, the same behaviour on both Ebest and Epop values is observed: CX in the first place, then OCPX, OX and finally PMX.

| Instance | OCPX |  |  | PMX |  |  | OX |  |  | CX |  |  |

Table 10. epop results for $10 \times 10$ instances.

Graphics 1 to 4 show the evolution over the generations of both the best individual (lower curves) and the mean population makespan (higher curves). X axis represents the number of generations and the Y axis the makespan values. A representative matrix instance was selected for each problem size according to the complexity level. The curves are obtained by averaging the results from the fifty experiments made for each instance. Mat40 instance was the one selected from $4 \times 4$ set (graphic 1). A superposition for all the crossover methods is observed among curves representing the progress of the best value; in particular with CX, the mean value curve is very near to the best value. In all instances, the mean population makespan remains constant and quite high through the generations with PMX and OX. Using CX and arriving to generation 200, an approaching to the best makespan found is observed, such a process of improvement continues in a notorious way as soon as the complexity of the problems is increased. Now, with OCPX the biggest approach to the best value found is detected between generations 100 and 150 , from this point on the mean population error does not vary so much.
In Mat40 instance (graphic 1), the evolution of the best individual is independent of the crossover method. In Mat51 (graphic 2), changes produced in the best individual are similar in CX, OX and OCPX, but in PMX the results are not so good as those showed by other crossover methods. In Mat79 and Mat101 instances, graphics 3 and 4 respectively, the curve representing the evolution of the best individual for CX is beneath others.

## 7. Conclusions

In this work we presented a simple evolutionary algorithm as an alternative technique to solve the open shop scheduling problem. The representation of solutions selected is a permutation of
operations. For that it was necessary to consider well-designed crossover and mutation operators in order to obtain feasible offspring after each mating action. Particularly, the crossover operators selected and contrasted were those proposed for the traveling salesman problem (TSP): partialmapped, order, cycle and one-cut point crossover. Some problem instances with different complexity level were used to evaluate the behaviour of our algorithm. Results from the application of different crossover methods were contrasted. Some observations and suggestions about the use of these algorithms were given.
Analyzing results obtained for instances with lesser complexity, we can remark that, regarding quality of results, OX provides better results than other crossover methods. When the instance complexity is increased, the algorithm using CX is the one that reaches solutions closer to the optimum value.
Independently of the instance complexity, we concluded that using CX operator levels of error in the population lower than employing the others crossover methods, were reached. However when that complexity is increased higher errors were shown.
Next steps will be oriented to develop more refined algorithms considering other representations, incorporating multiplicity characteristics that were applied to other scheduling problems.
