**Abstract**

The data collected by the L3 experiment at LEP at a centre-of-mass energy of 188.6 GeV are used to measure the W-pair production cross section and the W-boson decay branching fractions. These data correspond to an integrated luminosity of 176.8 $pb^{-1}$. The total cross section for W-pair production, combining all final states, is measured to be $\sigma_{WW} = 16.24 \pm 0.37$ (stat.) $\pm 0.22$ (syst.) pb. Including our data collected at lower centre-of-mass energies, the hadronic branching fraction of the W-boson is determined to be $B(W \to qq) = [68.20 \pm 0.68$ (stat.) $\pm 0.33$ (syst.)]%. The results agree with the Standard Model predictions. © 2000 Published by Elsevier Science B.V.

## 1. Introduction

Since 1996 the electron–positron collider LEP at CERN has exceeded the centre-of-mass energy required to produce W bosons in pairs, $e^+e^- \to W^+W^-$. To lowest order within the Standard Model [1,2] (SM), three Feynman diagrams contribute to W-pair production: $s$-channel $\gamma$ and Z-boson exchange and $t$-channel $\nu_e$ exchange, referred to as CC03 [3–5]. The W boson decays into a quark–antiquark pair, for example $W^- \to \bar{u}d$ or $\bar{c}s$, or a lepton–antilepton pair, $W^- \to \ell^-\bar{\nu}_\ell$ ($\ell = e, \mu, \tau$), in the following denoted as qq, $\ell\nu$ or ff in general for both $W^+$ and $W^-$ decays.

In 1998 the L3 detector [6] collected an integrated luminosity of 176.8 $pb^{-1}$ [7,8] at a centre-of-mass energy, $\sqrt{s}$, of 188.6 GeV, increasing our total W-pair statistics by a factor of four. Cross sections are measured for all four-fermion final states arising in W-pair production. The total W-pair production cross section is determined in a combined analysis. For the W-decay branching fractions, the results are combined with our previous measurements [9].

## 2. Analysis of W-pair production

The selections of W-pair events are based on the four-fermion final states from W-pair decays: $\ell\nu\ell\nu(\gamma)$, $qqe\nu(\gamma)$, $qq\mu\nu(\gamma)$, $qq\tau\nu(\gamma)$ and qqqq($\gamma$). Additional contributions to the production of these final states from other neutral-current (NC) or charged-current (CC) Feynman diagrams are small. At the current level of statistical accuracy the interference effects need to be taken into account only for $e^+e^- \to \ell\nu\ell\nu(\gamma)$ (CC56 + NC56) and $e^+e^- \to qqe\nu(\gamma)$ (CC20) [3–5].

The selection criteria are similar to those used for the data collected at $\sqrt{s} = 183$ GeV in 1997 [9] but are adapted to the higher centre-of-mass energy. In the following, only the main ideas and important changes are described. Particular emphasis is placed on the evaluation of systematic uncertainties.

For the identification of electrons, an energy deposition in the electromagnetic calorimeter is required, matched in azimuth with a track reconstructed in the central tracking system. Muons are identified either as a track reconstructed in the muon chambers pointing back to the interaction vertex or by their minimum-ionising-particle (MIP) signature in the central tracking system and calorimeters. Hadronic jets arising from $\tau$ decays are identified using a neural network based on topological variables: the number of tracks and calorimetric clusters associated to the jet, the half-opening angle of the jet, its electromagnetic energy and its mass. The jet clustering algorithm for a hadron-

ically decaying $\tau$ is based on geometrical clustering inside a cone of 15° half-opening angle [10]. For all other jets the Durham algorithm [11] is used. The sum of the four-momenta of the neutrinos in semileptonic, $e^+e^- \to qq\ell\nu(\gamma)$, and leptonic, $e^+e^- \to \ell\nu\ell\nu(\gamma)$, events is identified with the missing four-momentum of the event.

The following event generators are used to simulate the signal and background processes: KORALW [12], HERWIG [13] and ARIADNE [14] ($e^+e^- \to WW \to ffff(\gamma)$); EXCALIBUR [15] ($e^+e^- \to ffff(\gamma)$); PYTHIA [16] ($e^+e^- \to q\bar{q}(\gamma), ZZ(\gamma), WW(\gamma)$); KK2F [17] ($e^+e^- \to q\bar{q}(\gamma)$); KORALZ [18] ($e^+e^- \to \mu^+\mu^-(\gamma)$, $\tau^+\tau^-(\gamma)$); BHAGENE3 [19] and BHWIDE [20] ($e^+e^- \to e^+e^-(\gamma)$); TEEGG [21] ($e^+e^- \to e^+e^-\gamma(\gamma)$); DIAG36 [22] (leptonic two-photon collisions) and PHOJET [23] (hadronic two-photon collisions). The response of the L3 detector is modelled with the GEANT [24] detector simulation program which includes the effects of energy loss, multiple scattering and showering in the detector materials and in the beam pipe. Time dependent detector inefficiencies are taken into account in the simulation. The selection efficiencies are derived from Monte Carlo simulations fixing the mass and the width of the W boson to $m_W = 80.50$ GeV and $\Gamma_W = 2.11$ GeV, respectively.

### 2.1. $e^+e^- \to \ell\nu\ell\nu(\gamma)$

The event selection for the process $e^+e^- \to \ell\nu\ell\nu(\gamma)$ requires two high energy acoplanar leptons with large missing energy due to the neutrinos. The selection depends on whether the event contains zero, one or two identified electrons or muons, referred to as jet–jet, lepton–jet and lepton–lepton classes, where jet denotes a hadronic $\tau$-jet. The electron identification is improved by including also the SPACAL calorimeter that covers the polar angular region between the barrel and the end-cap BGO calorimeters.

A total of 190 events is selected: 116 lepton–lepton events, 64 lepton–jet events and 10 jet–jet events. The distribution of the energy of the highest-energy lepton in the lepton–lepton class and the distribution of the selected events in the different reconstructed final-state topologies are shown in Fig. 1.

The signal efficiencies are determined with four-fermion (CC56 + NC56) Monte Carlo samples and are quoted for the following phase-space cuts: $|\cos\theta| < 0.96$ for both charged leptons, where $\theta$ is the polar angle with respect to the beam axis, and energies greater than 15 GeV and 5 GeV for the higher and the lower energy lepton, respectively. Table 1 lists these efficiencies in the form of a 6-by-6 matrix, relating $\ell\nu\ell\nu$ events at generated four-fermion level to $\ell\nu\ell\nu$ events identified at reconstruction level. The overall selection efficiency in the full phase-space, based on a W-pair (CC03) Monte Carlo and under the assumption of charged-current lepton universality in W decays, is 52.3%. The background contributions, dominated by leptonic two-photon collisions and $e^+e^- \to \ell^+\ell^-(\gamma)$ events, are listed in Table 2.

### 2.2. $e^+e^- \to qq\ell\nu(\gamma)$

The selection of $e^+e^- \to qq\ell\nu(\gamma)$ events requires an identified high energy lepton, two hadronic jets with high particle multiplicity and missing momentum due to one or more neutrinos. The neutrino four-momentum vector is constructed by using the missing three-momentum vector, taken to be massless. In order to separate $qqe\nu(\gamma)$ and $qq\mu\nu(\gamma)$ events from $qq\tau\nu(\gamma)$ events for the case of a leptonic $\tau$ decay, the effective mass of the lepton–neutrino system is used. In the case of the $W \to e\nu$ and $W \to \mu\nu$ decay modes, the effective mass is peaked around the W mass, whereas for $W \to \tau\nu$ decays its value is typically much lower. The cut position is chosen such that the correlation among the cross sections of the three final states is minimised. The selection efficiencies and the background contaminations, dominated by $q\bar{q}(\gamma)$ events, are presented in Tables 1 and 2.

The $qqe\nu(\gamma)$ selection accepts 363 events. The distributions of the energy of the electron and of the electron–neutrino invariant mass are shown in Fig. 1. The signal efficiency for $qqe\nu(\gamma)$ events is determined from a four-fermion (CC20) Monte Carlo sample within the following phase-space cuts: $E_e, E_\nu > 15$ GeV, where $E_e$ and $E_\nu$ are the electron and neutrino energies; $|\cos\theta_e|, |\cos\theta_\nu| < 0.98$, where $\theta_e$ and $\theta_\nu$ are the electron and neutrino polar angles; $M_{e\nu}, M_{qq} > 45$ GeV, where $M_{e\nu}$ and $M_{qq}$ are the electron–neutrino and quark–quark invariant masses. These values are changed with respect to our previous analysis due to the increased centre-of-mass energy.

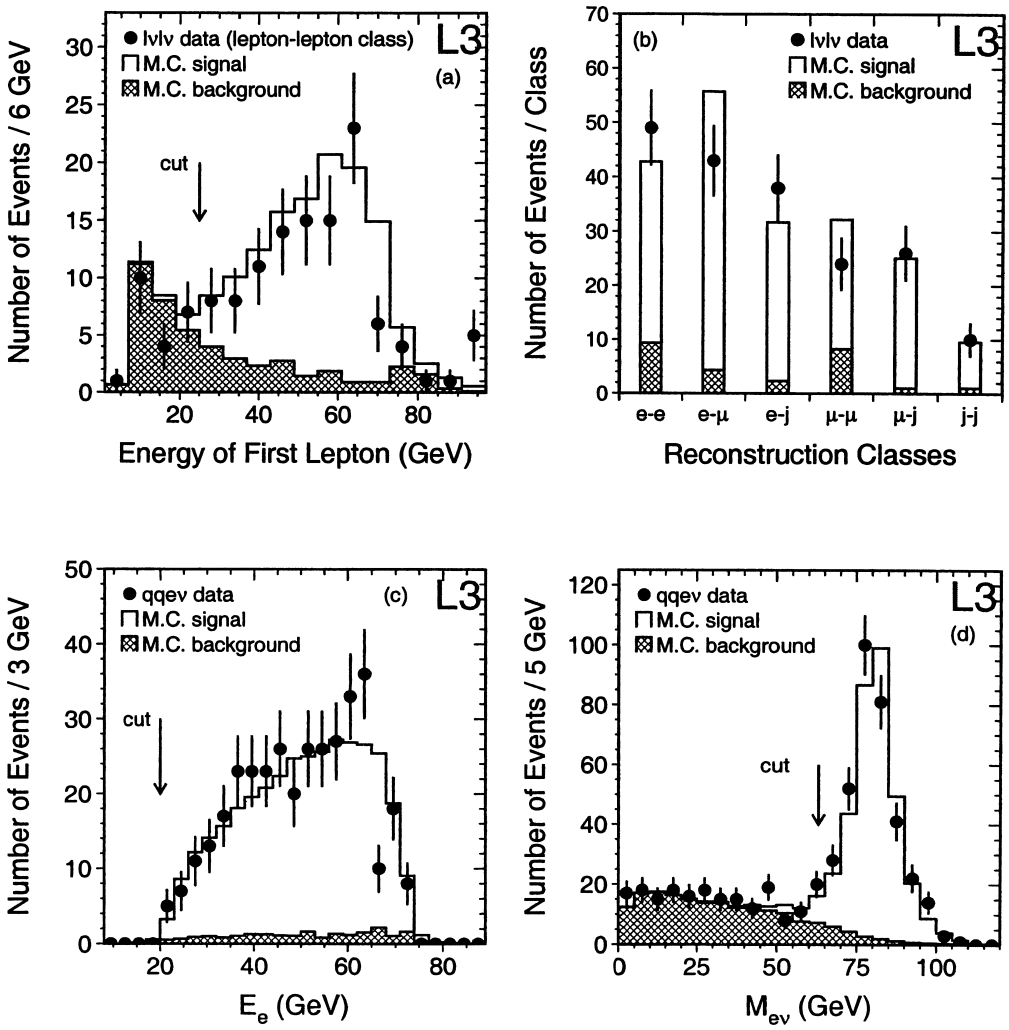

Fig. 1. Comparison of data and Monte Carlo distributions of variables used in the $e^+e^- \to \ell\nu\ell\nu(\gamma)$ and $e^+e^- \to qqe\nu(\gamma)$ selections. The background consists of non-$\ell\nu\ell\nu$/qqe$\nu$ processes. (a) The energy of the most energetic electron or muon in the lepton–lepton class. The vertical arrow indicates the cut position. The events in the plots have passed all other cuts. (b) The number of events in each final state topology (e = electron, $\mu$ = muon, j = hadronic $\tau$-jet) after all cuts. (c) The energy, $E_e$, of the electrons identified in the BGO calorimeter. (d) The invariant mass, $M_{e\nu}$, of the electron–neutrino system.

A total of 340 events are accepted by the $qq\mu\nu(\gamma)$ selection: 299 candidates with a muon reconstructed in the muon spectrometer and 41 with a muon identified by its MIP signature. The distributions of the momentum of the muon and of the variable $\alpha \sin\theta_\nu$, which discriminates against the $q\bar{q}(\gamma)$ background events, are presented in Fig. 2. The angle $\alpha$ is that between the direction of the muon and the nearest hadronic jet and $\theta_\nu$ is the polar angle of the neutrino.

A total of 329 $qq\tau\nu(\gamma)$ events are selected: 53 $\tau \to \nu e\bar{\nu}$, 50 $\tau \to \nu\mu\bar{\nu}$ and 226 $\tau \to \nu +$ hadrons candidates. The distributions of the jet–jet invariant mass and of the visible $\tau$ energy are shown in Fig. 2.

Table 1
Selection efficiencies for signal processes $e^+e^- \to \ell\nu\ell\nu(\gamma)$, $e^+e^- \to qq\ell\nu(\gamma)$, and $e^+e^- \to qqqq(\gamma)$. For the $\ell\nu\ell\nu$ and qqe$\nu$ selections, the signal efficiencies are derived from a CC56 + NC56 and a CC20 Monte Carlo sample, respectively, and given within phase-space cuts. The total efficiencies at CC03 level for the $\ell\nu\ell\nu$ and qqe$\nu$ selections are 52.3% and 78.1%, respectively. For the qqqq selection, the numbers are quoted for a neural-network output larger than 0.6

| Selection | Efficiencies (%) | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | e$\nu$e$\nu$ | e$\nu\mu\nu$ | e$\nu\tau\nu$ | $\mu\nu\mu\nu$ | $\mu\nu\tau\nu$ | $\tau\nu\tau\nu$ | qqe$\nu$ | qq$\mu\nu$ | qq$\tau\nu$ | qqqq |
| $e^+e^- \to e\nu e\nu(\gamma)$ | 64.2 | 0.3 | 12.6 | – | – | 1.1 | | | | |

### 2.3. $e^+e^- \to qqqq(\gamma)$

The $e^+e^- \to qqqq(\gamma)$ selection requires high multiplicity four-jet events with low missing energy. It accepts 94.8% of the WW $\to qqqq(\gamma)$ signal with a purity of 48.4%, corresponding to 2674 selected events. The measurement of jet energies and angles is improved by a kinematic fit that imposes four-momentum conservation.

A neural network is trained to further separate the signal from the main $e^+e^- \to q\bar{q}(\gamma)$ background, which is actually dominated by events with multi-gluon radiation. The input to the network consists of ten event variables: minimal and maximal jet energy, the energy difference between the two remaining jets, the minimal jet cluster multiplicity, the logarithm of the Durham jet-resolution parameter $y_{34}$ at which the event changes from a four-jet to a three-jet topology, the sphericity [25], the sum of the cosines of the jet–jet angles, the probability of the kinematic fit and the jet broadening of the most and

(a) The momentum, $P_\mu$, of the muons reconstructed in the muon chambers. (b) The variable $\alpha \sin\theta_\nu$ described in the text. (c) The invariant mass, $M_{jj}$, of the jet–jet system. (d) The energy, $E_\tau$, of the visible decay products of the $\tau$.

least energetic jets. The jet broadening is defined as $\sum \sqrt{p_t} / \sum \sqrt{p}$, where the sum is over the particles belonging to the jet, $p_t$ is the transverse momentum relative to the reconstructed jet axis and $p$ is the momentum of the particle. The distributions of four of these variables are shown in Fig. 3. The network is trained such that its output peaks at one for the signal and at zero for the background, as shown in Fig. 4.

The neural network output distribution for data events is fitted by a linear combination of outputs derived from Monte Carlo simulations for signal and background. A binned maximum likelihood fit is performed leaving both the signal and the most significant background ($e^+e^- \to q\bar{q}(\gamma)$) cross sections as free parameters. The latter is measured as $104.9 \pm 3.4$ pb, in agreement with both our measurement [8] and the SM value of 96.9 pb.

## 3. Systematic uncertainties

The systematic uncertainties taken into account in the determination of the results are summarised in Table 3. Common to all final states is the uncertainty on the integrated luminosity of 0.2% [8]. The Monte Carlo statistics for both signal and background processes affects mainly the $\ell\nu\ell\nu(\gamma)$ final states.

The uncertainty due to the selection procedure is evaluated by varying the positions of the selection cuts and interpreting the corresponding changes in the measured cross sections as systematic uncertainties. The systematic uncertainty on the neural network output in the $qqqq(\gamma)$ selection is estimated by recalculating the input variables of the neural network after smearing and scaling the measurements of energy depositions and tracks in the simulation according to the

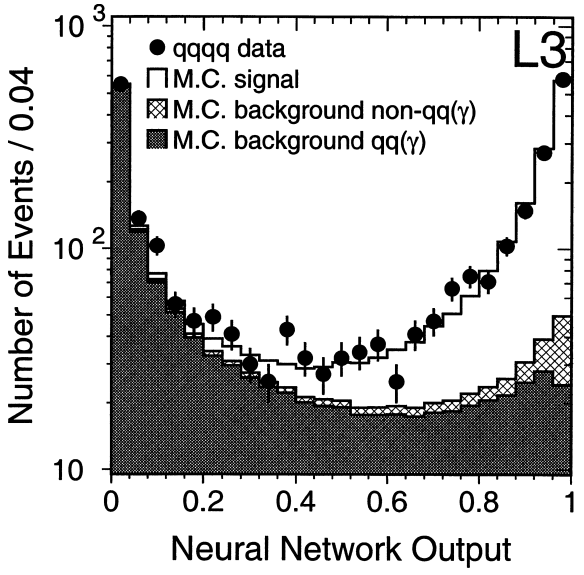

Fig. 4. Comparison of data and Monte Carlo distributions of the neural network output for selected $e^+e^- \to qqqq(\gamma)$ events.

uncertainty on their resolutions. In all selections, consistent results are found by studying the change in efficiency due to variations of the detector calibration within its uncertainty. The calibration is studied using samples of di-lepton and di-jet events, collected during the calibration runs at $\sqrt{s} = 91$ GeV and at higher energies. The trigger inefficiency as well as its uncertainty is found to be negligible. The systematic uncertainty assigned to the selection procedure is in the range 1.1% to 2.5% depending on the final state.

The theoretical uncertainties on the background cross sections, mainly on hadronic two-photon collisions (50%) and neutral-current four-fermion processes (5%), are propagated to the W-pair cross sections. The observed change of 0.1% to 0.3% is assigned as a systematic uncertainty. The KK2F Monte Carlo generator, instead of PYTHIA, is also used to simulate the $q\bar{q}(\gamma)$ background revealing no significant deviation on the measured cross section.

Table 3
Contributions to the systematic uncertainty on the cross section measurements (%). The systematic uncertainties are relative to the cross sections listed in Table 4

| Source | Final state | | | | |
|---|---|---|---|---|---|
| | $\ell\nu\ell\nu$ | qqe$\nu$ | qq$\mu\nu$ | qq$\tau\nu$ | qqqq |

| Total | 2.6 | 1.5 | 1.6 | 2.9 | 2.3 |

The dependence of the selection efficiencies on the mass and width of the W boson is studied using Monte Carlo samples simulated with different $m_W$ and $\Gamma_W$ values. The propagation of the world average uncertainties on these two parameters [26], 100 MeV on $m_W$ and 60 MeV on $\Gamma_W$, is taken as a systematic uncertainty and ranges from 0.1% to 0.3%.

The systematic uncertainty on initial-state radiation (ISR) due to its approximate (leading-log) treatment in KORALW is investigated by reweighting the energy and transverse momentum spectra of the ISR photons. This is done according to an exact $\mathcal{O}(\alpha)$ matrix element calculation [27] that also includes leading $\mathcal{O}(\alpha^2)$ contributions at small angles. This study shows that the associated systematic uncertainty on the cross section determination is negligible. For the $\ell\nu\ell\nu(\gamma)$ and $qqe\nu(\gamma)$ selections, the efficiencies are determined by using EXCALIBUR Monte Carlo events. To estimate the systematic uncertainty due to the restriction in the EXCALIBUR program to strictly collinear ISR photons, the KORALW generator, which includes both collinear and non-collinear ISR photons, is used. The change in the selection efficiency of KORALW events given by including or removing the non-collinear contribution is used as an estimate of the similar effect of neglecting such photons in EXCALIBUR. The $\ell\nu\ell\nu(\gamma)$ selection, requiring low activity in the regions of the detector away from the leptons, is sensitive to the transverse momentum of radiated photons. The resulting reduction of 0.5% absolute is applied as a correction to the EXCALIBUR efficiency and it is included in the results reported in Table 1. For the $qqe\nu(\gamma)$ final state, the correction turns out to be negligible. The total uncertainty on the correction in the $\ell\nu\ell\nu(\gamma)$ case, propagated to the cross section, amounts to 0.2% and is assigned as the systematic uncertainty due to ISR.

Final-state radiation (FSR) is absent in EXCALIBUR while it is implemented in KORALW by using the PHOTOS package [28] based on the leading-log approximation. A similar procedure as for ISR is then applied using the KORALW program to correct the efficiencies for the complete absence of FSR in EXCALIBUR in the case of the $\ell\nu\ell\nu(\gamma)$ and $qqe\nu(\gamma)$ selections. The correction amounts to a reduction in efficiency of 0.4% absolute for the $\ell\nu\ell\nu(\gamma)$ and 1.3% absolute for the $qqe\nu(\gamma)$ final states and is included in the results listed in Table 1. The effect on the $qqe\nu(\gamma)$ selection comes from its sensitivity to the electron isolation requirements affected by FSR photons. The PHOTOS package is inaccurate in the hard non-collinear region [28]. The related systematic uncertainty is estimated by determining the selection efficiencies using Monte Carlo signal events containing soft radiative photons only. Half of the difference with respect to the full radiation simulation, ranging from 0.2% to 0.9%, is taken as a systematic uncertainty.

The determination of the efficiency for the $qq\mu\nu(\gamma)$ and $qq\tau\nu(\gamma)$ selections, as well as the neural network output shape for the $qqqq(\gamma)$ channel, is based on a W-pair (CC03) Monte Carlo sample. This Monte Carlo neglects non-WW contributions interfering with the CC03 diagrams. In order to study the effect on the cross section, the CC03 Monte Carlo events are reweighted by the squared matrix element ratio of the full four-fermion calculation to the CC03 one. In the case of $qqqq(\gamma)$ selection, this reweighting procedure takes into account that the $ZZ(\gamma)$ final states are treated in the background subtraction. The difference in accepted cross section, in the range 0.1% to 0.4%, is taken as a systematic uncertainty.

The effect of modelling of the signal hadronisation is studied comparing the selection efficiencies based on simulated samples with different hadronisation schemes, JETSET [16], HERWIG [13] and ARIADNE [14]. The hadronisation parameters in these models were tuned to describe inclusive hadronic Z decays at $\sqrt{s} = 91$ GeV. No difference is observed for the $qqe\nu(\gamma)$ and $qq\mu\nu(\gamma)$ cross sections and the statistical accuracy of the test, 0.3%, is taken as a systematic uncertainty. In the case of the $qq\tau\nu(\gamma)$ selection, the treatment of hadronic jets and the tight requirements needed in order to identify the $\tau$ jet, lead to an uncertainty of 1.1%. In the $qqqq(\gamma)$ case a larger difference of 1.8%, dominated by the HERWIG comparison, is observed and assigned as the signal hadronisation uncertainty.

The hadronisation systematics due to the $e^+e^- \to q\bar{q}(\gamma)$ background is negligible for $qq\ell\nu$ final states. For the $qqqq(\gamma)$ selection it is estimated by two methods. In the first, a sample of HERWIG $q\bar{q}(\gamma)$ events is used instead of JETSET events. In the second, data and Monte Carlo distributions of hadronic Z decays collected at $\sqrt{s} = 91$ GeV are compared for the $y_{34}$ variable. The discrepancy is treated by reweighting Monte Carlo events to match the data as a function of $y_{34}$. The

resulting accepted $q\bar{q}(\gamma)$ cross section for a neural network output greater than 0.6 is increased by 4.8% relative to the JETSET prediction, while the signal cross section is decreased by 0.6%. These corrections are applied to the quoted results. From the uncertainty on the reweighting procedure and from the HERWIG–JETSET comparison, a 0.6% systematic uncertainty is assigned.

The modelling of Bose–Einstein correlations between hadrons from W decays may affect the selection efficiencies. In our recent study [29] we have measured the strength of intra-W Bose–Einstein correlations in semileptonic W decays. Its value is significantly different from zero and in good agreement with that for light-quark Z decays and with the LUBOEI [30] $BE_{32}$ and $BE_0$ predictions. The resulting systematic uncertainty is found to be negligible.

The same study shows that Bose–Einstein correlations between particles originating from different W bosons are strongly disfavoured in $qqqq(\gamma)$ events. Their strength is restricted to at most $1/4$ of the strength as simulated in the $BE_0/BE_{32}$ models with full correlations. The difference in the measured $qqqq(\gamma)$ cross section obtained by using Monte Carlo samples with intra-W only and with full inter-W correlations is rescaled by $1/4$ according to the allowed strength of inter-W correlations. The resulting difference of 0.3% is assigned as a systematic uncertainty. The uncertainty coming from the modelling of intra-W correlations is negligible as for the $qq\ell\nu(\gamma)$ case.

The influence of colour reconnection effects between the two hadronic systems arising in $WW \to qqqq(\gamma)$ decays are estimated using models implemented in ARIADNE (model 2) and PYTHIA 6.1 (models [31] SK I with reconnection parameter $k = 0.6$, SK II and SK II′). In all cases, the effect on the cross section is at the level of the statistical accuracy of 0.3%, which is then taken as the associated systematic uncertainty.

The total systematic uncertainty on the cross sections is estimated to be in the range 1.5%–2.9%, depending on the final state, from the combination of the above considered sources.

## 4. Results

The CC03 cross sections $\sigma_i$ of the ten signal processes $i$, or equivalently the W-decay branching fractions together with the total W-pair cross section, are determined simultaneously in maximum-likelihood fits [9]. For the $qqe\nu(\gamma)$ and the six $\ell\nu\ell\nu(\gamma)$ final states, where the non-W-pair processes have a significant contribution, the efficiencies are determined within the phase-space cuts described in Sections 2.1 and 2.2. The measured four-fermion cross sections are scaled by the conversion factors $f_i$, listed in Table 4, to obtain the CC03 cross sections. These factors are given by the ratio of the total CC03 cross section and the four-fermion cross section within phase-space cuts and are calculated with the EXCALIBUR Monte Carlo program.

The SM CC03 predictions are obtained using the GENTLE [32] program and also the new calculations implemented in the RacoonWW [33] and YFSWW3 [34] programs that include full $\mathcal{O}(\alpha)$ electroweak corrections, calculated in the double pole approximation [35]. The new predictions are about 2.5% lower than the GENTLE calculations, and have

Table 4
Conversion factors and cross sections of four-fermion final states. The ratio $f$ of the CC03 cross section without cuts and the four-fermion cross section within phase-space cuts is calculated with EXCALIBUR and listed in the second column. The third column shows the measured CC03 cross sections, $\sigma(\mathrm{CC03})$. The qqqq cross section is obtained from a fit to the neural-network output distribution as described in Section 2.3. The first uncertainty is statistical and the second systematic. Also shown are the SM predictions for the cross sections $\sigma_{\mathrm{SM}}$

| Process | Conversion factor $f$ | $\sigma(\mathrm{CC03})$ (pb) | $\sigma_{\mathrm{SM}}$ (pb) |
|---|---|---|---|
| $e^+e^- \to e\nu e\nu(\gamma)$ | 0.88 | $0.22 \pm 0.06 \pm 0.01$ | 0.19 |
| $e^+e^- \to e\nu\mu\nu(\gamma)$ | 1.07 | $0.22 \pm 0.07 \pm 0.01$ | 0.37 |
| $e^+e^- \to e\nu\tau\nu(\gamma)$ | 1.07 | $0.50 \pm 0.11 \pm 0.01$ | 0.37 |
| $e^+e^- \to \mu\nu\mu\nu(\gamma)$ | 0.96 | $0.10 \pm 0.06 \pm 0.01$ | 0.19 |
| $e^+e^- \to \mu\nu\tau\nu(\gamma)$ | 1.10 | $0.43 \pm 0.11 \pm 0.01$ | 0.37 |
| $e^+e^- \to \tau\nu\tau\nu(\gamma)$ | 0.96 | $0.20 \pm 0.09 \pm 0.01$ | 0.19 |
| $e^+e^- \to qqe\nu(\gamma)$ | 1.01 | $2.39 \pm 0.13 \pm 0.04$ | 2.37 |
| $e^+e^- \to qq\mu\nu(\gamma)$ | – | $2.27 \pm 0.14 \pm 0.04$ | 2.37 |
| $e^+e^- \to qq\tau\nu(\gamma)$ | – | $2.64 \pm 0.21 \pm 0.08$ | 2.37 |
| $e^+e^- \to qqqq(\gamma)$ | – | $7.36 \pm 0.24 \pm 0.18$ | 7.41 |

a reduced theoretical uncertainty of about 0.5% instead of 2% [36]. For numerical comparisons, RacoonWW predictions are used.

### 4.1. Signal cross sections

The ten measured CC03 signal cross sections $\sigma_i$ are listed in Table 4. They agree well with the SM expectations. The correlations between the measured cross sections, reported in Table 5, arise from non-vanishing off-diagonal terms in the efficiency matrix of Table 1. The systematic uncertainties shown in Table 3 and their correlations are taken into account in the determination of the results.

With the assumption of charged current lepton universality in W decays, the number of free parameters in the fit is reduced to three CC03 cross sections: $\sigma_{\ell\nu\ell\nu}$, $\sigma_{\mathrm{qq}\ell\nu}$, summed over all lepton species, and $\sigma_{\mathrm{qqqq}}$. Their values at $\sqrt{s} = 188.6$ GeV are determined to be:

$$\begin{aligned}
\sigma_{\ell\nu\ell\nu} &= 1.67 \pm 0.14 \pm 0.04 \text{ pb},\\
\sigma_{\mathrm{qq}\ell\nu} &= 7.20 \pm 0.24 \pm 0.08 \text{ pb},\\
\sigma_{\mathrm{qqqq}} &= 7.36 \pm 0.24 \pm 0.18 \text{ pb}, \qquad (1)
\end{aligned}$$

where the first uncertainty is statistical and the second systematic. The correlations between these three results are negligible.

### 4.2. W-decay branching fractions and W-pair cross section

The W decay branching fractions $B(\mathrm{W} \to \mathrm{ff})$ are derived in a combined fit with the total CC03 W-pair cross section. The sum of the branching fractions is fixed to be unity and their values are combined with our measurements at lower centre-of-mass energies [9] including correlations due to systematic uncertainties. The results are presented in Table 6, both without and with the assumption of charged current lepton universality in W decays. This hypothesis is supported by our results. The values for the assumption of lepton universality are:

$$\begin{aligned}
B(\mathrm{W} \to \mathrm{qq}) &= (68.20 \pm 0.68 \pm 0.33)\%,\\
B(\mathrm{W} \to \ell\nu) &= (10.60 \pm 0.23 \pm 0.11)\%. \qquad (2)
\end{aligned}$$

The relation between the W-decay branching fractions and the six elements $V_{ij}$ of the Cabibbo–Kobayashi–Maskawa quark mixing matrix $V_{\mathrm{CKM}}$ [37] not involving the top quark is [4]: $1/B(\mathrm{W} \to \ell\nu) = 3 + 3(1 + \alpha_s(m_W)/\pi)V^2$. Using $\alpha_s(m_W) = 0.121 \pm 0.002$ as the strong coupling constant, our measurement yields:

$$\begin{aligned}
V^2 &= \sum_{i=\mathrm{u,c};\ j=\mathrm{d,s,b}} |V_{ij}|^2\\
&= 2.065 \pm 0.064 \pm 0.032. \qquad (3)
\end{aligned}$$

Table 5
Correlation coefficients between the cross section measurements of single channels

| | $e\nu e\nu$ | $e\nu\mu\nu$ | $e\nu\tau\nu$ | $\mu\nu\mu\nu$ | $\mu\nu\tau\nu$ | $\tau\nu\tau\nu$ | $qqe\nu$ | $qq\mu\nu$ | $qq\tau\nu$ | qqqq |
|---|---|---|---|---|---|---|---|---|---|---|
| $e\nu e\nu$ | +1.00 | +0.09 | −0.37 | 0.00 | −0.01 | +0.05 | | | | |
| $e\nu\mu\nu$ | | +1.00 | −0.27 | +0.09 | −0.31 | +0.07 | | | | |
| $e\nu\tau\nu$ | | | +1.00 | −0.01 | +0.05 | −0.25 | | | | |
| $\mu\nu\mu\nu$ | | | | +1.00 | −0.32 | +0.03 | | | | |
| $\mu\nu\tau\nu$ | | | | | +1.00 | −0.18 | | | | |

| $qqe\nu$ | | | | | | | +1.00 | 0.00 | −0.10 | 0.00 |
| $qq\mu\nu$ | | | | | | | | +1.00 | −0.15 | 0.00 |
| $qq\tau\nu$ | | | | | | | | | +1.00 | −0.01 |
| qqqq | | | | | | | | | | +1.00 |

Table 6
W-decay branching fractions, $B$, and total W-pair cross section, $\sigma_{WW}$, derived without and with the assumption of charged-current lepton universality. The correlations between the leptonic branching fractions are $-0.03$, $-0.28$ and $-0.29$ for $e\mu$, $e\tau$ and $\mu\tau$, respectively. Also shown are the W-decay branching fractions [4] and the total W-pair cross section as expected in the SM

| Parameter | Lepton non-universality | Lepton universality | Standard Model |
|---|---|---|---|
| $B(W \to e\nu)$ (%) | $10.77 \pm 0.45 \pm 0.16$ | – | – |
| $B(W \to \mu\nu)$ (%) | $9.90 \pm 0.46 \pm 0.15$ | – | – |
| $B(W \to \tau\nu)$ (%) | $11.24 \pm 0.62 \pm 0.22$ | – | – |
| $B(W \to \ell\nu)$ (%) | – | $10.60 \pm 0.23 \pm 0.11$ | 10.83 |
| $B(W \to qq)$ (%) | $68.09 \pm 0.69 \pm 0.33$ | $68.20 \pm 0.68 \pm 0.33$ | 67.51 |
| $\sigma_{WW}$ (pb) | $16.29 \pm 0.37 \pm 0.22$ | $16.22 \pm 0.37 \pm 0.21$ | 16.24 |

Using the current world-average values and uncertainties of the other matrix elements [26], the value of $V_{cs}$ is derived as:

$$|V_{cs}| = 1.008 \pm 0.032 \pm 0.016. \quad (4)$$

This element is the least known of the two dominant diagonal elements appearing in $V^2$. The statistical uncertainty includes the uncertainties on $\alpha_s$ and the other $V_{ij}$ elements but is dominated by the statistical uncertainty on our measured W-decay branching fractions.

Assuming SM W-decay branching fractions [4], the total W-pair cross section at $\sqrt{s} = 188.6$ GeV is measured to be:

$$\sigma_{WW} = 16.24 \pm 0.37 \pm 0.22 \text{ pb}. \quad (5)$$

The measurements reported here are in agreement with recent measurements by other LEP experiments at the same centre-of-mass energy [38]. All our measurements of $\sigma_{WW}$ are compared with the SM expectation in Fig. 5. Good agreement is observed.

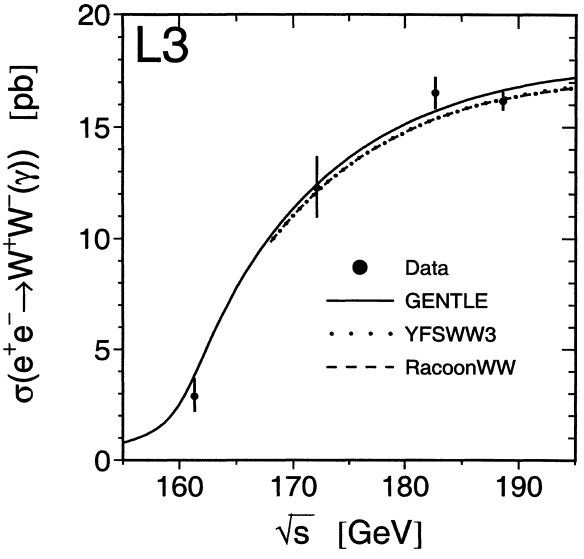

Fig. 5. The CC03 cross section of the process $e^+e^- \to W^+W^-(\gamma)$ as a function of the centre-of-mass energy. The published measurements at $\sqrt{s} = 161$, 172 and 183 GeV, and the new measurement at $\sqrt{s} = 189$ GeV are shown combining statistical and systematic uncertainties in quadrature. The curves show the SM expectation according to different calculations.

## Acknowledgements

We wish to express our gratitude to the CERN accelerator divisions for the excellent performance of the LEP machine. We acknowledge the contributions of the engineers and technicians who have participated in the construction and maintenance of this experiment.
