Abstract

Ductal carcinoma in situ (DCIS) is a noninvasive precursor lesion to invasive breast carcinoma. We still have no understanding on why only some DCIS lesions evolve to invasive cancer whereas others appear not to do so during the life span of the patient. Here, we performed full exome (tumor vs. matching normal), transcriptome, and methylome analysis of 30 pure high-grade DCIS (HG-DCIS) and 10 normal breast epithelial samples. Sixty-two percent of HG-DCIS cases displayed mutations affecting cancer driver genes or potential drivers. Mutations were observed affecting PIK3CA (21% of cases), TP53 (17%), GATA3 (7%), ML3 (7%) and single cases of mutations affecting CDH1, MAP2K4, TBX3, NFI, ATM, and ARID1A. Significantly, 83% of lesions displayed numerous large chromosomal copy number alterations, suggesting they might precede selection of cancer driver mutations. Integrated pathway-based modeling analysis of RNA-seq data allowed us to identify two DCIS subgroups (DCIS-C1 and DCIS-C2) based on their tumor-intrinsic subtypes, proliferative, immune scores, and in the activity of specific signaling pathways. The more aggressive DCIS-C1 (highly proliferative, basal-like, or ERBB2+) displayed signatures characteristic of activated Treg cells (CD4+/CD25+/FOXP3+) and CILIA4+/CD86+ complexes indicative of a tumor-associated immunosuppressive phenotype. Strikingly, all lesions showed evidence of TP53 pathway inactivation. Similarly, ncRNA and methylation profiles reproduce changes observed postinvasion. Among the most significant findings, we observed upregulation of IncRNA HOTAIR in DCIS-C1 lesions and hypermethylation of HOXAS and SOX genes. We conclude that most HG-DCIS lesions, in spite of representing a preinvasive stage of tumor progression, displayed molecular profiles indistinguishable from invasive breast cancer. Cancer Res; 75(18): 3980–90. ©2015 AACR.

Introduction

Ductal carcinoma in situ (DCIS) is by definition a precursor lesion to invasive ductal carcinoma (IDC). The routine use of screening mammography has led to a dramatic increase in DCIS detection during the last four decades (1). More than 62,000 cases per year account for about 25% of new breast cancers in the United States (1). Early retrospective studies concluded that women with biopsy proven DCIS have over a 10-fold higher risk for developing invasive carcinoma than women without DCIS history (2). If left untreated, it has been estimated that at least one-third of DCIS cases are likely to progress to IDC during the lifetime of the patient (1, 3). Regardless, it is beyond debate that the vast majority of IDCs results from the progression of precursor DCIS lesions (3). DCIS lesions are usually classified as either high-grade (HG-DCIS) or low-grade (LG-DCIS). Such distinction has limited impact on clinical management, as most patients with DCIS regardless of grade still receive similar treatment, which is either total mastectomy or segmental resection with radiation therapy (4–6). Recent studies argued that it is possible to identify more indolent DCIS lesions based on a small gene expression panel (Oncotype DX DCIS; ref. 7); however, concerns have been raised on the usefulness of such test and further validation is required (8, 9). Nevertheless, there is a great clinical need to identify those patients who can be spared radiation therapy after segmental resection, as it has been argued that many patients do not benefit from this likely overtreatment (10, 11).

Our current understanding of DCIS is that these are heterogeneous lesions and just like invasive carcinoma, DCIS lesions can be separated into different intrinsic subtypes on the basis of gene expression features (12–15). Mutations affecting genes such as TP53 and PIK3CA were also reported in DCIS (16, 17). However, as reviewed by Polyak, molecular signatures predictive of invasive progression have not been defined (18). In other words, we still have no understanding on why only some DCIS lesions evolve to invasive cancer whereas others appear not to do so. Importantly, no study to date has comprehensively delineated the molecular landscape of DCIS at the mutational, transcriptomic, and epigenetic levels in the same lesions and these are in part major goals of the present study.

Materials and Methods

Samples

Thirty fresh-frozen pure HG-DCIS cases with matched normal adjacent breast tissue samples were obtained from the MDACC.
Breast Tumor Bank. Normal breast tissue is defined as grossly unremarkable breast parenchyma away from the area of DCIS identified by imaging studies and gross evaluation and confirmed by subsequent histologic evaluation. These areas usually selected at least 1 cm and more away from the lesions. Patient tissue samples were collected after proper informed consents were obtained and protocols approved by ethical and institutional review boards. Ten cosmetic normal mammoplasty specimens were obtained from the Cooperative Human Tissue Network. Normal breast epithelial organoids were freshly isolated from the normal mammoplasty specimens as was previously described by us (19) and used for identification of differentially expressed genes (DEG) and differentially methylated genes (DMG) between normal and HG-DCIS samples.

DNA from 29 of 30 (97%) pure HG-DCIS samples and their paired normal breast tissue samples (total 58 samples) were subjected to exome capture sequencing analysis (Exome-Seq). DNA from 24 of 30 (80%) HG-DCIS samples and 5 normal breast organoids (total 29 samples) were subjected to reduced representation bisulfite sequencing analysis (RRBS). RNAs from 25 of 30 (83%) pure HG-DCIS and 10 normal breast organoids (total 35 samples) were subjected to RNA sequencing analysis (RNA-Seq; see Supplementary Table S1).

Histopathologic and immunohistochemical analysis

Histopathologic analysis of tumors and lymphocytic infiltrates were performed on hematoxylin and eosin (H&E)-stained sections. Intratumor-infiltrating lymphocytes (ITIL) are defined as intraepithelial mononuclear cells within DCIS cell th260/280 direct contact with cells (intralobular stroma) and are reported as the percentage of the tumor epithelial nests that contain infiltrating lymphocytes. Stromal tumor-infiltrating lymphocytes (STIL) are defined as the percentage of tumor stroma area that contains lymphocytic infiltrates without direct contact to DCIS cells. All samples were analyzed for estrogen receptor (ER)/progesterone receptor (PR) by immunohistochemistry using standard procedures.

Exome-Seq analysis

DNA from 29 DCIS samples and their paired normal breast tissue samples (n = 58 samples) were purified using the DNeasy Blood and Tissue Kit (Qiagen). Only DNA samples with 260/280 ratios greater than 2.0 were processed for library construction using the SPRIWorks Fragment Library Kit I (Beckman Coulter). Four libraries were pooled together and processed for exome capture using the NimbleGen SeqCap EZ Human Exome Library v3.0 (HG19, Roche), covering more than 23,000 genes and ~64 Mbp, 76-nt paired-end sequencing was performed using an Illumina HiSeq2000 platform and obtained about 40 million tags per sample. The short sequenced reads were mapped to the human reference genome (hg19) by the splice junction aligner TopHat (25). We used several R/Bioconductor packages to accurately calculate the gene expression abundance at the whole-genome level using the aligned reads (SAM files) and to identify differentially expressed genes between normal and DCIS samples. Briefly, the number of reads mapped to each gene on the basis of the UCSC hg19 KnownGene database were counted, reported, and annotated using the GenomicFeatures, Rsamtools, and org.Hs.eg.db packages. Raw datasets have been submitted to NCBI GEO database with accession number GSE69994. To identify differentially expressed genes between normal breast epithelium and DCIS samples, we used the edgeR-test on the basis of the normalized number of reads mapped to each gene (26).

Pathway-based analysis was performed using the PARADIGM software at the Firec Genomics server (default options; discretization bounds of 33%) on the basis of the normalized gene expression profiles of the deregulated transcripts between normal and DCIS samples [false discovery rate (FDR) < 0.01; log fold change (FC) > ±1] expressed in log2 counts per million (27). PARADIGM produces a data matrix of integrated pathway activities (IPA), this data matrix was used in place of the mRNA expression profiles to identify the topmost variable IPAs among samples. Heatmap visualization of differentially expressed
transcripts and IPAs were done with the MultiExperiment Viewer software (MeV v4.9; ref. 28). Intrinsic subtype classification of DCIS samples into luminal-like, basal-like, ERBB2-enriched, and normal-like groups was performed using the 50-gene (PAM50) predictor bioclassifier R script (29). We used the ESTIMATE algorithm (Estimation of Stromal and Immune cells in Malignant Tumors using Expression data) to infer the immune and stromal components from each DCIS sample (30).

Bioinformatic analysis of The Cancer Genome Atlas-BRCA dataset

To perform a comparative analysis of the mutational, gene expression, methylation, and pathway activities profiles identified in DCIS with invasive stages, we analyzed invasive breast cancer (IBC) datasets obtained from the The Cancer Genome Atlas (TCGA)-BRCA project (31). The clinical (including PAM50 subtypes from RNAseq) and preprocessed data (IBC-gene-level mutation, IBC-gene expression Illumina HiSeq, IBC DNA methylation 450K and IBC Paradigm RNAseq + CNV profiles) were retrieved from the Cancer Genomics Browser (https://genome-cancer.soe.ucsc.edu/) and cBioPortal (http://www.cbioportal.org/). Data integration and visualization were done with R and MeV software, respectively.

Results and Discussion

Fresh-frozen pure DCIS samples are extremely difficult to obtain, as all tumor materials are submitted for routine histopathologic evaluation with formalin fixation and paraffin embedding. Only cases with available frozen tissue samples are usually those from large palpable DCIS cases, which tend to be HG-DCIS. Nevertheless, we were able to gather from our Institution’s breast tumor bank a group of fresh-frozen “pure” HG-DCIS samples (i.e., with no evidence of invasion in the same breast) and matching normal pairs and subjected them to a thorough characterization involving whole Exome-Seq, RRBS, and RNA-Seq. We also generated RNA-Seq and RRBS data from breast epithelial organoids obtained from normal mammaryplasty specimens for identification of differentially expressed genes and differential methylated genes between normal and DCIS lesions.

Significantly mutated genes and DNA copy number variations in DCIS

Exome-Seq data on 29 pure DCIS normal matched pairs indicated a median of 75% targeted genome loci having at least 40× coverage. We detected 2,908 single-base substitutions, including 1,324 nonsynonymous (missense) SNVs, 46 stop gain, 2 stop loss, 16 mutations at splicing sites, 151 noncoding RNA (ncRNA) mutations, and 1,369 SNVs encoded synonymous (silent) mutations (Fig. 1A; Supplementary Table S2). Almost 50% of these mutations were C>T;G>A transitions in agreement with the previously described most prevalent mutation-type signature in breast cancer (Fig. 1A; ref. 32). We also detected 24 frameshift deletions, 10 frameshift insertions, and 43 non-frameshift deletion/insertion events. Every single DCIS displayed a significant number of mutations. The total mutation rate was 1.61 mutations per Mb on average with a range of 0.8 to 3.8 mutations per Mb (Fig. 1B), indicating that some DCISs have quite higher mutation rates than others. We identified somatic mutations affecting at least 10 genes reported as mutated at a ≥2% rate in IBC (33). In total, 18 of 29 HG-DCIS cases (62%) displayed mutations affecting one or combinations of targets described as cancer driver genes or potential drivers. Among these, we detected mutations affecting PIK3CA (21%), TP53 (17%), GATA3 (7%), MLL3 (7%) and single cases of mutations affecting CDH1, MAP2K1, TBX3, NF1, ATM, and ARID1A (Fig. 1B). The comparative frequency of these mutations in pure DCIS and the TCGA database on IBC (n = 976 cases as per September 2014) is shown in Fig. 1C. Similarly to IBC previous gene mutation data (31, 33), the most frequently mutated genes are PIK3CA (6 cases; 4 of them affecting ER/PR-positive cases) and TP53 (5 cases; 4 of them affecting ER/PR negative cases). Only one case displayed mutations in both genes. Interestingly, several genes reported as mutated in IBC, such as MAP3K1, PTEN, AKT1, RUNX1, RB1, and various others so far, have not been detected mutated in DCIS, suggesting that perhaps some of these mutations may be associated with postinvasion events; however, our sample number is still limited. In summary, we observed that 100% of pure HG-DCIS display numerous somatic mutations, but only a subgroup display mutations affecting cancer driver genes or potential drivers. Nevertheless, the mutational profile in pure HG-DCIS is extremely similar to that observed at invasive stages with only a moderate lower frequency of mutation for cancer driver genes. As we performed RNA-Seq in parallel, the identified mutations were validated by allele-specific RNA-Seq data.

Somatic copy number variations (CNV) were estimated using Exome-Seq data to predict regions of genomic alterations such as amplification, gains, and losses (23). Figure 1D summarizes the overall frequency of DNA gains/losses affecting all chromosome arms among DCIS samples. The profile of copy number changes across the genome in HG-DCIS is practically identical to profiles reported in invasive breast lesions (34) and is in agreement with early observations using comparative genome hybridization (CGH) approaches (35). In our approach, however, we were able to define with more precision the genomic regions spanning the CNV (Supplementary Table S2). The most common regions of increased DNA copy number include chr1q, chr8q, chr17q, and chr20q and regions of common copy number loss include regions chr8p, chr11q, chr17p, and chr22q (Fig. 1D; Supplementary Fig. S1 and Supplementary Table S2). Regions of potential focal amplification were also identified, including ERBB2, VEGFA, MYC, AURKA, MDM2, FGFR1, and CCND1 (Fig. 1B and Supplementary Table S2).

Among the most important conclusions of the CNV analysis is that 83% (24 of 29) of DCIS lesions displayed evidence of large chromosomal alterations; only in 5 samples (T9, T15, T28, T30, and T31), large chromosomal copy number changes were not detected (Supplementary Table S2). Interestingly, multiple cases (T2, T4, T5, T10, T13, T16, T22, and T24) displayed significantly large chromosomal copy number alterations but no mutations in known cancer driver genes, whereas 16 of 18 cases (89%) with mutations in cancer driver genes all show significant chromosomal copy number alterations (Fig. 1B; Supplementary Table S2). Importantly, in only 3 of 29 (10%) HG-DCIS (T9, T15, T28), no large chromosomal abnormalities or mutations in putative cancer driver genes were detected. Nevertheless our findings also suggest that large chromosomal copy number alterations (trisomies, monosomies, large chromosomal duplications, and deletions) occur early in tumor progression, perhaps preceding the selection of alleles with mutations in driver genes.
Gene expression analysis of coding RNAs

Whole-transcriptome unsupervised analysis from RNA-Seq data demonstrates a clear segregation of normal breast epithelium and DCIS samples on the basis of similarity distances (measured in leading logFC) from dimension 1 in a multidimensional scaling plot (MDS; Fig. 2A). More importantly, DCIS samples were clustered into two subgroups (cluster 1 or DCIS-C1 and cluster 2 or DCIS-C2) according to the positive and negative distances from MDS dimension 2.

We observed that the ER/PR status determined by immuno-histochemistry and their intrinsic subtypes predicted by using the 50-gene PAM50 model (29) were significantly associated with

Figure 1.

Mutations and copy number alterations in DCIS samples. A, types of single-base substitutions and InDels identified by Exome-Seq analysis. B, driver and co-driver mutations in DCIS samples. Each column represents one DCIS case and each row represents the number of mutations in each gene per tumor. Blue squares, + mutation. Genes shown with an asterisk are rarely mutated in IBC (<2%); however, they are noted as possible co-drivers events, as they are found either in the SANGER Cancer Gene Census database or have significant potentially carcinogenic biological functions. C, comparative frequency of mutations of driver/co-driver mutations in pure DCIS (red bars) and the TCGA database on IBC (blue bars). D, CNVs among DCIS samples. Chromosomal gains (red, up) and losses (green, down) as percentage of occurrence in the respective region are indicated.
each identified DCIS cluster (P < 0.001). Sixty-seven percent of the cases in DCIS-C1 were ER/PR double negative and basal-like or ERBB2⁺ with high proliferative scores. On the other hand, 100% of the cases in DCIS-C2 were ER/PR double positive, luminal-like with low/moderate proliferative scores (Fig. 2B).

Statistical analysis of RNA-Seq data revealed 5,985 transcripts differentially expressed between normal and DCIS samples (FDR < 0.01; logFC > ±1), 95% were coding RNAs and 5% were ncRNAs. Among the deregulated genes, 885 were differentially expressed between both DCIS clusters (FDR < 0.01; logFC ≥ ±1; Supplementary Table S3). To identify bioprocesses that differentiate DCIS-C1 from the DCIS-C2, we performed functional enrichment and pathway activity analyses. Gene ontology (GO) analysis of deregulated transcripts between DCIS clusters revealed specific functional modules characteristic for each of both subgroups: a functional module strongly related to immune (P < 1.46E⁻³⁵) and inflammatory (P < 6.4E⁻¹⁹) responses clearly associated to the DCIS-C1 group and a module related with response to steroid
hormones (P < 9.1E−4) associated to the DCIS-C2 group (Fig. 2C and Supplementary Fig. S2). In addition, functional annotation analysis identified "T-cell differentiation", "B-cell activation", "angiogenesis," "negative regulation of apoptosis," and "ECM remodeling" to be highly associated with DCIS-C1-modulated genes. Given the aforementioned strong association with immune-related themes, we performed a blind evaluation of lymphocytic infiltrates on H&E sections of all DCIS samples determining iTIL and sTIL scores. Supporting the GO and functional annotation observations, DCIS-C1 samples showed a significantly higher number of iTILs (P < 0.01) than the DCIS-C2 counterparts. Similarly, a gene expression signature–based method known as ESTIMATE (30) predicted higher immune scores on DCIS-C1 versus DCIS-C2 (P < 0.001; Fig. 2D).

Further analysis of the behavior of the 885 deregulated transcripts that discriminate both DCIS clusters within the TCGA breast cancer dataset demonstrated that a large number of genes (~80%) identified as upregulated in the DCIS-C1 group remained upregulated in basal-like and ERBB2+ breast cancers compared with the luminal A/B subtypes (Fig. 2E). This is in itself very significant, and similarly to the above described mutational and CNV analyses, it indicates that most of the gene expression changes characteristic of IBC are already present at the pure DCIS (preinvasive) stage.

Pathway-based representation analysis (PARADIGM; ref. 27) of deregulated transcripts identified a plethora of signaling pathways that differ in their activity between normal and DCIS samples, such as API, TNF, TP53, FOXM1, MYB, and E2F1/DP1 pathways (Fig. 3A; Supplementary Table S3). It was striking to observe that the TP53 signaling pathway was found deactivated in all DCIS samples analyzed regardless of TP53 mutation status, ER/PR expression status or intrinsic subtype when compared with normal epithelium (Fig. 3B). Since on the basis of mutational evidence is currently believed that TP53 inactivation is mostly a feature of the basal-like intrinsic subtype (31, 33), we were surprised by our finding, thus we decided to perform a pathway-based analysis focused on the TP53 pathway exclusively in the existing TCGA IBC dataset. Interestingly, PARADIGM analysis based on TCGA-BRCA RNA-seq and CNV profiles predict that TP53 pathway inactivation is a common theme affecting well above 85% of breast cancers regardless of intrinsic subtypes (and as consequence also regardless of TP53 mutation status; Supplementary Fig. S3). Nevertheless, this novel information on TP53 pathway inactivation in most breast cancers should be taken with caution and requires further validation.

In the DCIS-C2 cases, the activity of the E2/ER pathway was the predominant signature (Supplementary Fig. S2), whereas in the DCIS-C1 subgroup, the HES1 and HIF1A/ARNT pathways were more frequently activated. Interestingly, the HIF1A/ARNT was previously identified as one of the key regulatory features associated with basal-like carcinomas (31).

More importantly, PARADIGM analysis identified that 80% of DCIS-C1 cases showed activity of Treg cells (CD4+/CD25+/FOXP3+) and CTLA4+/CD86+ complexes (Fig. 3C). These results are revealing, as a growing body of evidence indicates that the outcome of an immune response toward a tumor is largely determined by the specific characteristics of the infiltrating lymphocytes. A tumor-directed immune response involving cytolytic CD8+ T cells, T-helper 1 cells (Th1), and natural killer (NK) cells appears to protect against tumor development and progression, whereas activation of humoral immunity involving B cells and/or Th2 responses appear associated to protumorigenic phenotypes (36). Suppression of antitumor immune response by inducing T-cell anergy due Th2-polarized activity and/or expansion of Treg cells (CD4+ CD25+ FOXP3+) with a subsequent loss of T-cell-mediated cytotoxicity, together with the development of angiogenesis and tissue remodeling could be instrumental for promoting the progression of HG-DCIS to the infiltrating stages. Recently, Kristensen and colleagues (37) suggested that the perturbation in the immune response and IL signaling (IL4, IL6, IL12, and IL23) can lead to classification of IBC subclasses with prognostic value. Patients who have basal-like breast carcinomas are characterized

Figure 3. Pathway activities analysis in DCIS samples versus normal mammary epithelium. A, PARADIGM inferences of the most variable integrated pathway activities using the normalized gene expression profiles of the deregulated transcripts between normal and DCIS samples. B, TP53 pathway activity was found systematically deactivated in both DCIS groups compared with normal epithelium (P < 0.001). C, PARADIGM analysis identified increased activities of Treg cells (CD4+/CD25+/FOXP3+) and CTLA4+/CD86+ complexes in DCIS-C1 compared with DCIS-C2 samples (P < 0.001).
by high expression of protumorigenic T\textsubscript{h}2/humoral-related genes and a low T\textsubscript{h}1/T\textsubscript{h}2 ratio. In addition, the immune response and IL signaling identified in IBC appears also prominent in DCIS (37). Importantly, the IPA described in our study indicates that DCIS-C1 lesions are characterized by a tumor-associated immunosuppressive phenotype, suggesting a protumorigenic polarization of the immune response. In other words, DCIS-C1 lesions bear all the immunomodulatory characteristics of invasive breast lesions, thus indicating that the host immune defenses (tumor rejection responses) have been or are in the process of being defeated.

**Gene expression analysis of noncoding RNAs**

RNA-Seq analysis allowed us to identify 193 long noncoding RNAs (lncRNA) as differentially expressed between normal and DCIS samples ($P < 0.01$, FDR $< 0.01$). 127 of which were antisense RNAs and 66 were long intergenic noncoding RNAs (lincRNA; Fig. 4A and B). Eighty-seven percent of the identified lncRNAs (168 of 193) were upregulated in DCIS (Supplementary Table S4). Interestingly, 46 of the 127 antisense RNAs and 18 of the 66 lincRNAs have been recently identified as potentially relevant in breast cancer (38). The Genomic Regions Enrichment of Annotations Tool (GREAT) resource was used to evaluate the correlation between deregulated lncRNAs and their neighboring genes (39). We found that 52% of the mRNA genes in the vicinity of the affected lncRNAs were also deregulated (Supplementary Table S4), and most of them (80%) showed a positive association with the expression of the lncRNAs, which would indicate that deregulation of cis-acting lncRNA prevails in DCIS. Among the deregulated lncRNAs in DCIS, we found HOTAIR (HOX transcript antisense RNA; logFC $= +5.03$; FDR $= 1.92\times 10^{-8}$) and HOTAIRM1 (HOXA transcript antisense RNA myeloid–specific 1; logFC $= -1.90$; FDR $= 8.63\times 10^{-7}$; Fig. 4C). HOTAIR and HOTAIRM1 expression levels were positively correlated with the expression of their adjacent HOXC (located at chr12q13.13) and HOXA (located at chr7q15.2) gene clusters, respectively (Fig. 4D). Recent studies have shown that lncRNAs can be associated with enhancer regions, leading to increased activity of neighboring genes (40). One of the best-known lncRNAs, HOTAIR, found significantly upregulated in DCIS-C1 lesions, was suggested to promote breast cancer metastasis and shown to be pervasively overexpressed in most human cancers when tumor tissue was compared with adjacent noncancerous tissue (41). HOTAIR interacts with and recruits the Polycomb-repressive complex 2 (PRC2) and regulates chromosome occupancy of EZH2 (a subunit of PRC2), which leads to histone H3 lysine 27 trimethylation of the HOXD locus and subsequent silencing of this gene cluster. On the other hand, HOTAIRM1, found significantly downregulated in many DCIS lesions (particularly DCIS-C1), was shown to play a role in the regulation of gene expression during retinoic acid–induced myeloid differentiation preventing the induction of HOXA genes (42). Mechanistically, our data indicate that HOTAIR and HOTAIRM1 may act by modulating HOX gene expression in trans and cis during early stages of breast cancer progression. This is the first study demonstrating that these lncRNAs are deregulated "early" at preinvasive stages of breast cancer progression. The remaining lncRNAs (LINC000277, LINC00861, LINC00578, LINC00426, and others shown in Supplementary Table S4) would constitute a novel group of lncRNAs deregulated in the transition normal DCIS.

In addition, we were able to identify 36 differentially expressed pri/pre-miRNAs among the deregulated noncoding transcripts between normal and DCIS as well. We detected MIR3606 (logFC $= +6.58$), MIR4728 (logFC $= +4.25$), and MIR503HG (logFC $= +2.91$) among the most upmodulated small noncoding RNAs in DCIS samples. Interestingly, MIR4728 was specifically upmodulated in DCIS-C1 samples (logFC $= +2.28$). MIR4728 gene is located at chr17q12 and encoded within intron 24 of the ERBB2 gene (43). Recently, Newie and colleagues demonstrated that ERBB2 amplification might lead to ESR1 downregulation through internal seed interaction with mir-4728-3p in breast cancer cells (44). We corroborate this observation identifying a positive

**Figure 4.** Gene expression profile of deregulated lncRNAs. A, pie chart displaying the types of lncRNAs differentially expressed between normal and DCIS samples. B, heatmap of deregulated lncRNAs where black lines on the right indicate potentially relevant transcripts in IBC as was determined by Su and colleagues (38). C, box and whisker plots representing HOTAIR and HOTAIRM1 expression levels among normal and DCIS samples. D, transcriptomic coexpression analysis using HOTAIR and HOTAIRM1 as templates identified significant positive correlations with the expression of their neighboring HOXC (located at chr12q13.13) and HOXA (located at chr7q15.2) gene clusters, respectively ($r > 0.7$ and $P < 0.0001$).
correlation between ERBB2 and MIR4728 expression ($r = 0.90; P < 0.01$) in DCIS samples in agreement with the CNV data.

On the other hand, MIR260 ($\text{logFC} = -4.62$), MIRNA221 ($\text{logFC} = -3.55$), MIR22/MIR22HG ($\text{logFC} = -2.34$), MIR3661 ($\text{logFC} = -2.07$), and MIR17HC ($\text{logFC} = -1.94$), among others, were detected as downmodulated in DCIS samples. The human MIR22 gene is located in a minimal LOH region on chromosome 17 close to TP53. MIR22 has been reported to be downregulated in hepatocellular, lung, colorectal, ovarian and breast cancer, acting as a tumor suppressor (45). Furthermore, MIR22 overexpression induces growth suppression and senescence-like phenotypes in human breast epithelial and breast cancer cells (46). MIR17HC is the host gene for the MIR17-20 cluster (a group of at least six miRNAs) located at 13q31 that function as a tumor suppressor in human breast cancer by decreasing AIB1 and cyclin D1 expression (47). The MIR17-20 cluster is known to inhibit breast cancer cellular proliferation through G1-S cell-cycle arrest (48). Our study suggests that gain and loss of expression of key regulatory miRNAs in normal breast epithelium might constitute important early procarcinogenic events conducive to overcome the barrier imposed by senescence and limited cell proliferation. However, further studies on the profiling of the mature miRNAs in normal and DCIS samples are needed to corroborate the aforementioned observations.

DNA methylation analysis

RRBS data analysis coupled with RNA-Seq profiling allowed us to identify the most relevant methylation events associated to the development of DCIS lesions. We identified 1,103 DMGs between normal breast epithelia and DCIS samples (Supplementary Table S5), mapping at distal (8% at $-4$ kb to $-2$ kb relative to TSS), proximal promoter regions (56% at $-2$ kb to $+500$ bp) or the gene body (36% at $+500$ to $+2$ kb) of 311 loci (Fig. 5A). Among these 1,103 DMGs, 1,029 were hypermethylated and 74 were hypomethylated CpG islands in DCIS samples. Functional enrichment analysis of the hypermethylated regions in DCIS identified
showed a significant downmodulation in IBC compared with normal samples (Supplementary Fig. S4). In a recent study, it was shown that the SOX10 protein is predominantly expressed in basal-like breast carcinomas compared with the other subtypes (52). However, TCGA data analysis clearly showed that SOX10 was downmodulated in luminal-like and ERBB2+ breast cancer subtypes compared with normal tissue samples (Supplementary Fig. S4). Fu and colleagues (50) demonstrated that silencing of SOX17 due to promoter hypermethylation is frequent in invasive carcinomas and may contribute to aberrant activation of Wnt signaling in breast cancer. This evidence raises the possibility that hypermethylation of specific SOX family members could constitute common important epigenetic phenomena occurring at early stages of breast cancer development that deserves further study.

Interestingly, in our dataset, HOXA5 hypermethylation was more frequently associated with the DCIS-C1 group, characterized by the presence of tumors with basal-like/ERBB2 intrinsic subtypes (Fig. 5D). TP53 gene expression has been shown to be under the control of HOXA5 in breast cancer cells (53). Reduced HOXA5 protein levels correlate with the lack of p53 expression, supporting the concept that HOXA5 may act as a tumor suppressor via activation of p53 expression. HOXA5 has also been shown to be a strong positive regulator of PR (54). It is also important to note that 4 of 5 cases with TP53 non-synonymous mutations were detected in ER/PR double negative tumors from the DCIS-C1 group (T3, T7, T26, and T29). Overall, these data suggest that TP53 mutation and HOXA5 hypermethylation could constitute early events during breast cancer progression that can cooperate to inactivate the TP53 pathway in more prone to progress DCIS lesions. In addition our pathway-based analysis indicated that TP53 pathway inactivation is an extremely common feature in practically all HG-DCIS lesions and HOXA5 methylation could be one of the more relevant causative mechanisms. CpGI methylation and expression analysis from the TCGA breast cancer dataset demonstrated that HOXA5 hypermethylation and downregulation can be also identified and is common in more advanced stages of breast cancer progression (Fig. 5E and F).

Concluding Remarks

Comprehensive characterization of pure HG-DCIS lesions at the genome, transcriptome, and methylome levels allowed us to identify the most relevant changes occurring at a preinvasive stage of breast cancer progression. A comparison of the mutation and chromosomal copy number alteration profiles identified in these pure in situ lesions with previous observations reported by the TCGA study on IBC, revealing expected similarities with IBC (e.g., PIK3CA, TP53, GATA3). However, it was striking to observe that practically all known major genomic abnormalities are already present at preinvasive stages at high frequency mutation rates and 83% of lesions displaying very large copy number chromosomal alterations. In only 10% of lesions we did not detect large chromosomal changes or mutations in so-called cancer driver genes. More importantly, at the transcriptional level, pathway-based analysis pointed to TP53 pathway inactivation as extremely common in DCIS regardless of tumor intrinsic subtype. We also observed that deregulation of genes associated with the suppression of the antitumor immune response are hallmarks of a HG-DCIS subgroup (highly proliferative basal-like or ERBB2+ tumors), displaying profiles very similar to those found at invasive and metastatic stages. In addition, we identified novel and relevant regulatory circuits significantly deregulated in DCIS that were not previously reported and that involve coding and noncoding transcripts (e.g., HOTAIR, HOTAIRM1). Our comprehensive catalogue of differentially expressed genes is also consistent with the existence of the most common breast cancer subtypes, but now we show that these important and complex epigenetic changes, such as hypermethylation of HOXA5 and specific SOX genes, are already operating at the in situ stage. Our findings clearly indicate that a subgroup of HG-DCIS lesions can be identified displaying more aggressive molecular profiles, more importantly however is that most, if not all, HG-DCIS lesions displayed profiles indistinguishable from IBC.

Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.

Authors’ Contributions

Conception and design: A.A. Sahin, C.M. Aldaz
Development of methodology: J. Shen, A.A. Sahin
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): J. Lee, Y. Takata, J. Shen, M.R. Estecio, C.M. Aldaz
Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): M.C. Abba, T. Gong, Y. Lu, Y. Zhong, E. Lacunza, M. Butti, A.A. Sahin, C.M. Aldaz
Writing, review, and/or revision of the manuscript: M.C. Abba, T. Gong, E. Lacunza, M. Butti, J. Shen, C.M. Aldaz
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): M. Butti, S. Gaddis, C.M. Aldaz
Study supervision: C.M. Aldaz

Grant Support

This study was supported by CPRIT Core Facility Support Grant RP120348 and the MD Anderson’s Institutional Tissue Bank, award RP30CA1016672 from the NCI and additionally by grant NIH/NCI R01CA102444 (C.M. Aldaz).
